INTRODUCTION

The progress in our understanding of early events in the development of colonic neoplasia is the result of 2 advances: (1) improved characterization of lesions detected at endoscopy and (2) new knowledge about the molecular biology of nonpolypoid lesions. Improved characterization of neoplastic lesions has been achieved through the addition of chromoscopy[1-5] and high-resolution endoscopy with magnification and image processing.[6-9] New molecular knowledge about both sessile serrated lesions and flat adenomas has altered our understanding of the histogenesis of nonpolypoid lesions and their endoscopic management. A multidisciplinary workshop held in February 2008 in Kyoto, Japan, explored new aspects of our knowledge. This text summarizes the debate and ultimately the consensus among experts in endoscopy, pathology, and molecular biology of the colon.

In 1975, Muto et al[10] described the histologic transition from a precursor adenomatous polyp to a confirmed colorectal cancer. Previous opinion, that colorectal cancer develops through a single pathway, has now been challenged, and it is clear that colorectal cancer can develop through multiple pathways, as reviewed by Jass[11] and Jass et al.[12] The morphology of premalignant colonic lesions depends on the direction of proliferating cell growth. Essentially, 3 types of lesions are now recognized: polypoid, nonpolypoid, and depressed. Polypoid lesions grow above the surface of the mucosa, rather than below, and the volume of the polypoid component appears to correlate with the histologic stage, as shown in the large series issued from endoscopy and pathology units in Japan and listed in the Paris classification.[13,14] Nonpolypoid lesions may grow flat or slightly elevated and, eventually, may grow and progress to polypoid lesions or to laterally spreading tumors. Depressed lesions deserve special attention because of the difficulty in their detection, the need for special techniques (mucosectomy) to remove them by endoscopy, and a recognized increased risk of rapid progression to cancer, independent of size, as shown in endoscopy and pathology units in Japan.[13,14] Nonpolypoid, depressed lesions progress in depth rather than above the surface of the mucosa, and submucosal invasion is frequent, even for small lesions (Figs. 1 and 2).

Sporadic colorectal neoplasia results from the disruption of normal cellular growth and senescence at a molecular level. In 1990, Fearon and Vogelstein[15] demonstrated that a mutation within the adenomatous polyposis coli (APC) tumor-suppressor gene initiated one of the major neoplasia pathways. This mutation was linked to chromosomal instability (CIN) and loss of heterozygosity (LOH). Subtle molecular differences cause alternative growth patterns, such as polypoid or nonpolypoid (including the flat adenoma and flat cancer), and they, subsequently, will be discussed.

In the last decade, the serrated pathway has been described as an alternative pathway to colorectal cancer. Serrated lesions refer both to hyperplastic (HP) (nonneoplastic) lesions, often called HP polyps, and sessile serrated lesions, often called sessile serrated adenomas (SSAs); the latter are considered the precursor for microsatellite instable (MIS) cancers. An early event in the growth of sessile-serrated lesions is an inactivating mutation within the BRAF gene encoding the B-RAF protein kinase. Progression from nondysplastic sessile-serrated lesions to neoplasia requires epigenetic silencing of hMLH1, one of the mismatch repair (MMR) genes. Inactivating methylation of hMLH1 disrupts the MMR cascade, which results in the accumulation of mutations in a variety of genes, some of which lead to neoplasia and MIS cancers.

ENDOSCOPIC CLASSIFICATION OF POLYPOID AND NONPOLYPOID SUPERFICIAL LESIONS

The morphology of superficial neoplastic or nonneoplastic lesions in the colorectal mucosa is protruding (polypoid) or flat (nonpolypoid). Premalignant and malignant

Abbreviations: ACF, aberrant crypt foci; APC, adenomatous polyposis coli; CIMP, CpG-Island methylation phenotype; CIN, chromosomal instability; FAP, familial adenomatous polyposis; HGIN, high-grade intraepithelial neoplasia; HNPCC, hereditary nonpolyposis colon cancer; HP, hyperplastic; LOH, loss of heterozygosity; LST, laterally spreading type; m, mucosa; MIS, microsatellite instable; MMR, mismatch repair; MSS, microsatellite stable; NBI, narrow-band imaging; sm, submucosa; SSA, sessile serrated adenoma; TSA, traditional serrated adenoma.

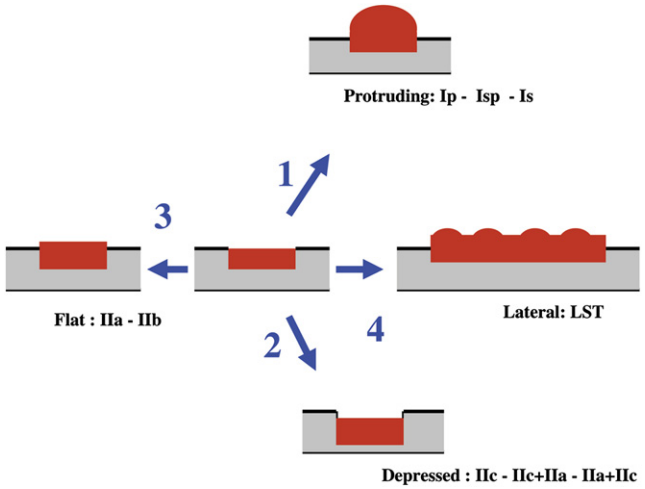

Figure 1. Models of tumor growth during the development of colorectal neoplasia: Progression occurs in 4 distinct models: (1) as a polypoid protruding lesion in an upward direction, (2) as a nonpolypoid depressed lesion, which progresses in a downward direction in depth, (3) as a nonpolypoid lesion, which remains either flat or slightly elevated, and (4) As a LST lesion.

TABLE 1. Morphologic classification of type 0 lesions with superficial appearance at colonoscopy (Paris-Japanese classification)

Polypoid type*	Pedunculated (0-Ip)
	Sessile (0-Is)
	Mixed (0-Isp)
Nonpolypoid type	Slightly elevated (0-IIa)
	Completely flat (0-IIb)
	Slightly depressed (0-IIc)
Mixed types	Elevated and depressed (0-IIa + IIc)
	Depressed and elevated (0-IIc + IIa)
	Sessile and depressed (0-Is + IIc)

*Polypoid lesions are elevated more than 2.5 mm above the surrounding mucosa. Nonpolypoid lesions are flat, elevated less than 2.5 mm, or are depressed less than 2.5 mm. Slightly elevated lesions should not be mistaken for sessile or flat lesions.

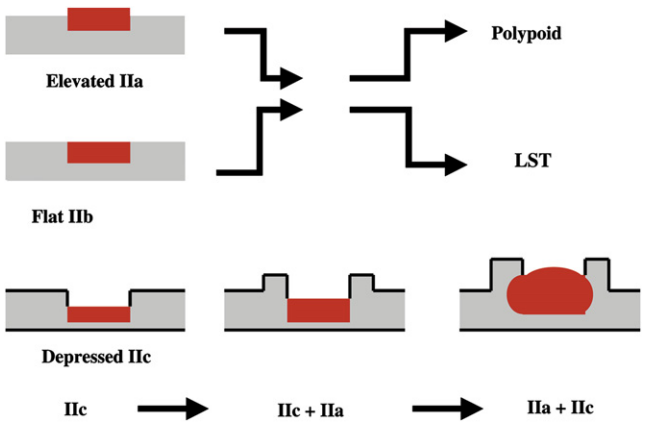

Figure 2. Subtypes of nonpolypoid neoplastic lesions. The nondepressed types, elevated or completely flat (0-IIa, 0-IIb), are stable or progress to polypoid or LST lesions. The depressed type (0-IIc) may progress to a mixed morphology, 0-IIc + 0-IIa and then 0-IIa + 0-IIc. When the tumor increases in depth, the surface of the depression may be elevated, even in small lesions.

neoplastic lesions of the digestive mucosa are called superficial when their appearance at endoscopy suggests that their depth is limited to the mucosa (m) or submucosa (sm). Nonpolypoid (flat) small neoplastic lesions are frequent in human beings, and some of them show a fast progression to cancer, in spite of maintaining a small size. In the absence of adenomatous remnants, these lesions appear to be "de novo" cancer. The nonpolypoid model of neoplastic growth is confirmed in animal studies, because it can occur spontaneously in baboons[16] or after administration of the carcinogen dimethyl hydrazine in rats.[17,18] Nonprotruding carcinomas may be found throughout the colon, whereas protruding carcinomas are more prevalent in the distal portion of the colon.

The endoscopic morphology of superficial neoplastic lesions was described by Japanese endoscopists and was classified into various subtypes: category 0 refers to superficial invasion, whereas categories I to V correspond to advanced cancer with invasion deeper than the submucosa. The Paris classification[13,14] is similar to the Japanese classification, as illustrated in Table 1. Polypoid lesions may be pedunculated (0-Ip), sessile (0-Is), or with a mixed pattern (0-Isp). Nonpolypoid lesions are either slightly elevated, termed 0-IIa (elevation <2.5 mm above the level of the mucosa), completely flat (0-IIb), or slightly depressed (0-IIc). Completely flat and depressed lesions are rare in the colonic mucosa, whereas slightly elevated lesions are more prevalent. Excavated (0-III) superficial lesions are extremely rare in the colon. Slightly depressed (0-IIc) lesions are especially important to recognize, because they often harbor invasive cancer, despite their small diameter. The morphology of superficial neoplastic lesions is shown in the Image Atlas.

In the colon and the rectum, the distinction between polypoid and nonpolypoid lesions and the specific character of depressed lesions was extensively explored in Akita and in Yokohama by Kudo.[19-25] An accurate analysis is hampered by multiple factors that can be controlled if the endoscopist and the pathologist describe the gross morphology of endoscopic or surgically resected specimens in the same subtypes of the Paris classification.[13,14]

First, nonpolypoid lesions are less conspicuous than polypoid lesions, so they are often missed, especially by those endoscopists who are not trained in techniques used in the East. Recent series with high-definition video endoscopes may provide more reliable estimations. Second, nonpolypoid, slightly elevated (0-IIa) lesions are

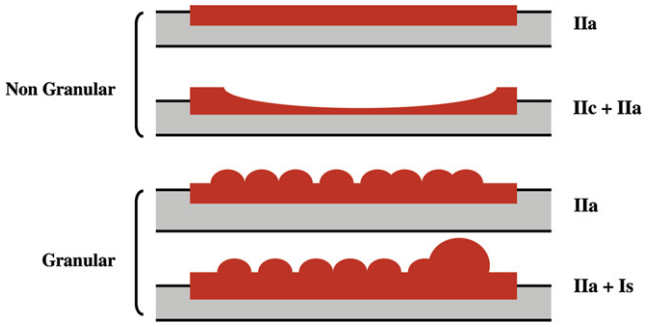

Figure 3. LST lesions. Models of granular and nongranular LST of neoplastic lesions, with the corresponding classification according to the categories of the Paris classification.

often misclassified as sessile (0-Is). For example, 1505 superficial neoplastic lesions found in the National Polyp Study[26] and previously classified as polypoid were reviewed in light of the new terminology. After revision, there were 802 polypoid pedunculated lesions, 229 polypoid sessile lesions, and 474 nonpolypoid lesions (31.4%) called flat. The proportion of severe neoplasia in this group is very low (1.3%), but no distinction was made among elevated, completely flat, or depressed subtypes. Third, all subtypes of nonpolypoid lesions are often called ''flat lesions,'' without distinguishing the important, but rare, depressed lesions, which frequently are invasive cancers. Fourth, nonpolypoid neoplastic lesions may show a mixed pattern of both a polypoid sessile and a nonpolypoid morphology in distinct sectors. Laterally spreading type (LST) lesions, which were described by Kudo[24] in relation to their transversal mode of growth, should be further distinguished based on their granular or nongranular, homogenous or nonhomogenous appearance. Their relationship to the categories of the Paris classification is often a source of confusion. Some LST lesions can be classified as nonpolypoid, in the subtypes 0-IIa or 0-IIa + IIc. Other LST lesions associate with a polypoid (0-Is) or a nonpolypoid pattern. Some nongranular subtypes of LST are called pseudodepressed, to underline the distinction from simple depressed 0-IIc lesions (Fig. 3, Table 2).

TABLE 2. Subtypes of LST lesions: morphologic classification of LST lesions and their correspondence in the Paris-Japanese classification*

Subtypes of LST	Classification in type 0
LST granular	
Homogenous type	0-IIa
Nodular mixed type	0-IIa, 0-Is + IIa, 0-IIa +Is
LST nongranular	
Elevated type	0-IIa
Pseudodepressed type	0-IIa + IIc, 0-IIc + IIa

*The term ''laterally spreading type (LST)'' refers to the lateral growth of lesions at least 10 mm in diameter; this is in opposition to traditional polypoid (upward growth) or flat and depressed lesions (downward growth).

HISTOLOGIC CLASSIFICATION OF ADENOMAS AND CARCINOMAS

Adenoma

An adenoma is a premalignant lesion that shows intraepithelial neoplasia without invasion of the mucosal stroma and is always associated with cytologic neoplasia. The identification of an adenoma is based on 2 types of alterations: structural and cytologic. The structural or architectural features include simple-to-complex crowding of glands, lateral expansion, and irregularity. According to their architecture, adenomas are classified as tubular, tubulovillous, or villous types: at least 20% of the estimated volume of the lesion should be villous to classify an adenoma as tubulovillous and 80% villous to be defined as a villous adenoma; all other adenomas are classified as tubular. In the Vienna classification, an adenoma with marked structural alterations is classified as high-grade intraepithelial neoplasia (HGIN)[27,28] (Table 3). Cytologic features of cell atypia consist of 2 to 5 rows of palisading or enlarged nuclei, with a dispersed chromatin pattern and prominent nucleoli. High-grade cytologic abnormalities, with a loss of polarity, stratification, and atypical mitotic figures, usually coexist with architectural alterations and may be difficult to distinguish from intramucosal carcinoma.

The clinical relevance of the terminology ''advanced adenoma,'' often used in endoscopic series, is linked to a significant risk of progression to cancer and demands a prompt treatment decision. Advanced adenomas are either large lesions, at least 10 mm in diameter (endoscopic criteria), or adenomas, with a villous architecture, or HGIN (histologic criteria).

Adenocarcinoma

An intramucosal adenocarcinoma is characterized by the invasion of neoplastic cells in the stroma of the tunica (lamina) propria. Extension to the submucosa across the muscularis mucosae characterizes submucosal adenocarcinoma. The term ''early'' colorectal cancer includes both intramucosal and submucosal adenocarcinomas. Extension beyond the submucosa defines ''advanced'' cancer. If a carcinoma is contained completely within the mucosa, the risk of lymph-node and vascular invasion is nil; as a rule, endoscopic resection is a legitimate treatment for those lesions. If there is submucosal invasion, then extension to endothelium-lined vascular spaces is regarded as a significant risk for lymph-node invasion or distant metastases. Risk increases in proportion to the depth and width of invasion in the submucosa. When invasion is slight, endoscopic treatment may be legitimate; when invasion is extensive, surgery is required. The boundary between endoscopic or

TABLE 3. Histopathologic classification of superficial neoplastic lesions of the colorectal mucosa

Pragmatic classification*		Correspondence to Vienna classification	Clinical relevance
Normal mucosa or inflammation hyperplasia (metaplasia)	No neoplasia	Negative for neoplasia	Endoscopic treatment
		Indefinite for neoplasia	
Low-grade neoplasia	Noninvasive (low-grade and high-grade adenoma)	Noninvasive low-grade IEN	
		Noninvasive high-grade IEN	
		Indefinite for invasive	Endoscopic or surgical treatment
	Invasive† (low-grade carcinoma; no risk factors)	Mucosal carcinoma or submucosal carcinoma	Surgical treatment
High-grade neoplasia	Invasive (high-grade carcinoma with risk factors)	Mucosal carcinoma or submucosal carcinoma	

IEN, Intraepithelial neoplasia.
*This pragmatic classification applies to the adenoma-adenocarcinoma sequence and to neoplasia in serrated lesions. Risk factors for the progression of cancer include one of the following: vessel permeation, incomplete polypectomy and/or resection, poor differentiation, marked budding of tumor cells, or infiltration equal or deeper than the lower third of the submucosal layer. Risk factors are absent in low-grade invasive cancer and present in high-grade invasive cancer. Low-grade intramucosal neoplasia is treated with legitimacy by endoscopy. High-grade intramucosal neoplasia, identified on cytologic characters, may require a more radical treatment.
†(1) Invasive: in stroma of mucosa or submucosa; (2) intraepithelial neoplasia (IEN); (3) signet-ring-cell carcinoma is equivalent to high grade neoplasia.

surgical treatment can be estimated before treatment, but confirmation of its legitimacy is retrospective when the pathologist examines the complete operative specimen.

Pathologists have proposed various methods of estimation of the degree of invasion in the submucosa in superficial cancer. Pedunculated lesions were graded by Haggitt et al,[29] and sessile lesions were graded by Kudo[21] and Kudo et al[22] and Kikuchi et al[30]; the latter system can also be adapted for nonpolypoid lesions. For example, the risk of lymph-node metastases is 2%, 8%, and 23% for Kikuchi levels sm1, sm2, and sm3 (the upper, middle, and lower level of the submucosa), respectively. The ability to estimate the depth of submucosal invasion in resected nonpolypoid lesions has become more precise with the development of strip mucosectomy and submucosal dissection.

For most endoscopic resection specimens, dividing the submucosa into 3 parts is not applicable, because the limit of the muscularis is not included. A precise assessment of the depth of invasion requires a micrometric measurement from the lower part of the muscularis mucosae to the limit of invasion. This method has been adopted in Japan, where 1000 μ is the lower limit for which adequate endoscopic treatment can be assumed. In daily practice, the pathologist can estimate the depth of invasion in the submucosa as sm1 if less than half of the segment of submucosa is included within the specimen; as sm2, if the invasion is beyond this limit; and as sm3, if the cancer is positive at the cut margin. One can also estimate invasion in depth in 3 levels (sm1, sm2, sm3) and in transversal extension just below the muscularis mucosae in 3 levels (sm1a, sm1b, sm1c). This double measurement is adopted in the analysis of the neoplastic lesions that are resected at the Yokohama endoscopy unit in Japan. A slight invasion of the submucosa corresponds to sm1a or sm1b. An extensive invasion corresponds to transverse extension sm1c or to levels sm2 and sm3 in depth.

Flat adenocarcinoma and de novo cancer

For more than 2 decades, Japanese endoscopists have been giving special attention to nonpolypoid flat or depressed adenomas[31,32] and to flat minute adenocarcinomas[33-35] similar to minute gastric cancers.[36] Particular attention was given by Kudo et al[19-21] and Kudo and Muto[25] to the specific differences between flat and depressed lesions in the colorectal mucosa. A cancer is called de novo when it is assumed to develop without an adenomatous precursor.[37] In spite of being small, and even inconspicuous, such lesions are evolutive and often should be treated by surgery.

The quest for adenomatous remnants in colorectal cancer

Various studies, based on analysis of operative specimens, suggest that a substantial proportion of colorectal adenocarcinomas develop de novo[38-48]: the figures range from 20% to 90%, averaging around 40%. In Japan, the proportion of adenoma remnants was analyzed in relation to morphology. In specimens of early cancer, Shimoda et al[37] showed that the polypoid morphology was frequent (82%) and included adenomatous remnants in 91% of cases (133 of 146); nonpolypoid morphology was less frequent and never included adenoma remnants (0 of 32). The average diameter of nonpolypoid early cancer was smaller, and invasion in the submucosa was more frequent. In contrast,

TABLE 4. Grade of superficial colorectal cancer in Japan*

	Carcinoma with low or high malignancy	
	Low grade	**High grade**
Cytologic parameters		
Cellular atypia	Low proportion	High proportion
K67 labeling cells	Low index	High index
Depth of invasion		
Intramucosal	Most cases	Few cases
Submucosal	Few cases	Most cases
Morphology		
Polypoid	Most cases	Few cases
Depressed	Few cases	Most cases

*Well-differentiated intramucosal or submucosal cancer is classified on cytologic criteria as low-grade or high-grade malignancy. The majority of submucosal cancer is "high grade." The majority (80%-85%) of intramucosal cancer is "low grade." Low-grade intramucosal cancer is also called high-grade adenoma. The term "cancer" is maintained for high-grade intramucosal neoplasia and for submucosal lesions.

the same investigators showed a high (78.2%) proportion of nonpolypoid cancer in 853 operative specimens of advanced cancer, and they estimated that around 80% of colorectal cancers arise as de novo. Kuramoto and Oohara,[43] in 1995, observed the absence of adenoma remnants in 89.7% of flat early cancers (87 of 97) and in only 16.6% of polypoid early cancers (23 of 138). Submucosal invasion occurred in 53.6% of flat early cancers and in 13.8% of polypoid early cancers. Kaneko et al[47] analyzed the morphology of 107 specimens and confirmed that tumors with a nonpolypoid morphology were smaller (33 vs 55 mm in diameter), with a higher proportion of vascular invasion (95% vs 74%). In Europe, Eide[44] found adenoma remnants in 53% of polypoid cancers and in only 12% of nonpolypoid cancers. Bedenne et al[38] estimated that 40% of cancer arose de novo from the analysis of 1630 operative specimens; adenoma remnants were present in 25.8% of protruding tumors and in only 0.5% of ulceroinfiltrative tumors (0.5%). George et al[45] estimated the proportion of de novo cancers at 48% from an analysis of 186 advanced cancers; adenoma remnants were found in 52% of polypoid and in only 2% of nonpolypoid cancers.

Other histopathologic studies based on endoscopic features of the flat, de novo, early colorectal cancers led to a similar conclusions. Goto[46] classified 83 cases of early cancers in 2 types: polypoid (84% of cases) and flat, de novo cancers, without adenoma remnants (22.9% of cases). Kuramoto and Oohara[42] analyzed the morphology of 37 flat early cancers and found frequent invasion in the submucosa, in spite of the small size of the lesions.

Legitimacy of the terminology de novo cancer

In the colorectal mucosa, a de novo cancer is assumed to develop without an adenomatous precursor.[37] This assumption relies primarily on the absence of adenomatous tissue in small and flat malignant lesions, but, it is also possible that malignant transformation has obliterated any remnant of a flat or depressed small adenoma. The hypothesis of the direct malignant growth is supported by the very low occurrence of adenoma remnants in flat early cancer and by the shift in the proportions of the polypoid and nonpolypoid morphology in early versus advanced cancers.

Regardless, a de novo cancer is characterized by a nonpolypoid growth pattern, a smaller size, and a more frequent invasion into the submucosa.[40] Flat adenocarcinomas are characterized by specific molecular events that begin in their early stage. The de novo colorectal cancers represent a small fraction of early cancers but will account for a higher proportion of advanced cancers, with most estimates being in the range of 40%. By using a cohort of patients distributed in 3 groups, that is, negative colonoscopy, polyps, and cancer, Chen et al[39] estimated the dwelling time to cancer in the classical adenoma-carcinoma sequence and in the de novo sequence by a Markov analysis. Their analysis suggests that at least 30% of colorectal cancers arise from the de novo sequence.

Low-grade and high-grade adenocarcinoma

The distinction between low-grade and high-grade adenocarcinoma currently used in Japan applies only to well-differentiated tumors, and the grade is established on cytologic rather than on structural criteria (Table 4), as shown by Ajioka et al[33] and Maeo et al.[48] Low-grade and well-differentiated adenocarcinomas show hyperchromatic and elongated nuclei, in basal arrangement, limited to two thirds of the epithelium and are less evolutive and less invasive than high-grade tumors. High-grade and well-differentiated adenocarcinomas show an increased crowding of round, large, and irregular nuclei, migrating up to the apical pole of epithelial cells and an increased mitotic index, and tend to be more invasive, with possible lymph-node invasion, even when intramucosal. With immunochemistry, high-grade tumors show a high index of Ki-67–labeled cells or, alternatively, an increased expression of proliferating cell nuclear antigen,[48] a diffuse expression of beta-catenin, an adhesion protein that binds cadherin, and a higher expression of dysadherin, a cell-membrane glycoprotein. A positive immune-labeling of CD-10 may indicate a higher risk for liver metastasis.[49]

Immunostaining with dysadherin and beta-catenin was explored by Shimoda (unpublished data, 2008) at the National Cancer Center, Tokyo, in 128 superficial neoplastic colorectal lesions (adenoma or carcinoma), classified into the high-grade or low-grade types. Dysadherin expression was lower in adenoma (32%) than in cancer, in which the rates were 58% and 83% for low-grade and

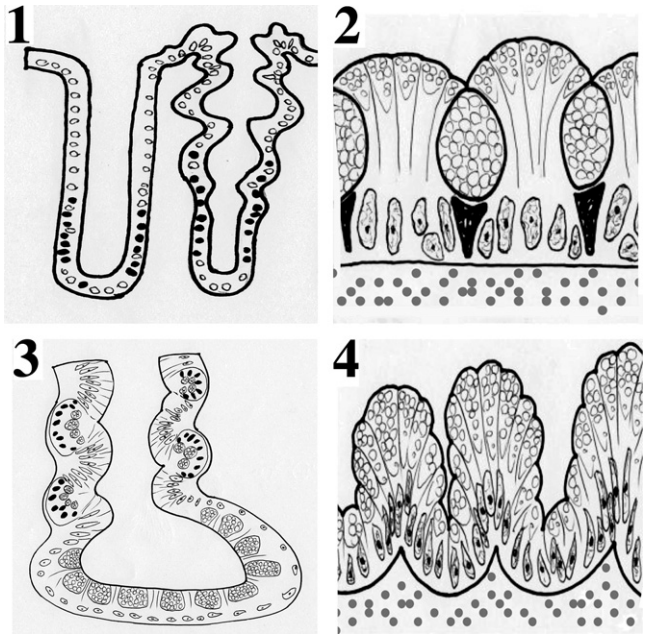

Figure 4. Representation of serrated lesions: (1) HP lesion (notched crypt lumen, cell multiplication, and growth in the ''bottom-up'' direction), (2) another HP lesion (goblet-rich type with normal cell nuclei), (3) Sessile serrated lesion (a crypt with a notched lumen, discontinuous proliferation zones, horizontal spread of basal crypt with mature goblet cells), often called a sessile serrated adenoma, and (4) Another sessile serrated lesion: increased mucus, elongated nuclei (by J. R. Jass).

high-grade intramucosal cancer, respectively, and were 50% and 74% for submucosal cancer, respectively. In addition, the diffuse expression of beta-catenin was absent in adenomas and was frequent in cancer, in which the proportions were 27% and 72% for low-grade and high-grade intramucosal cancer, respectively, and 50% and 79% for low-grade and high-grade submucosal cancer, respectively. The majority of intramucosal cancers are ''low grade,'' whereas most submucosal cancers are ''high grade.'' The distinction between low-grade and high-grade differentiated adenocarcinoma is relevant to the legitimacy of a local excision. Low-grade intramucosal or submucosal cancer is safely treated by endoscopic resection. High-grade cancer (even intramucosal) deserves special management, and surgery may offer a legitimate alternative to endoscopic treatment.

Vienna classification

Some discrepancies between Western and Eastern pathologists deserve emphasis: (1) low-grade or high-grade structural alterations of the epithelium, without invasion of the stroma, have been called dysplasia; the tendency is now to substitute this term with that of ''noninvasive intraepithelial neoplasia''; (2) The World Health Organization definition of colonic adenocarcinoma (in contrast to the Japanese experience) requires a confirmation of invasion into the submucosa; intramucosal carcinoma is then classified as HGIN and will not be included in cancer registries. The Vienna classification, and its revised edition,[27,28] achieves a relative consensus between Western and Eastern experts and classifies the severity of epithelial alterations in the mucosa, as well as the extension to the submucosa, as shown in Table 3: (1) negative for neoplasia, (2) intramucosal neoplasia with noninvasive low-grade intraepithelial neoplasia and HGIN and with invasive HGIN, and (3) submucosal adenocarcinoma.

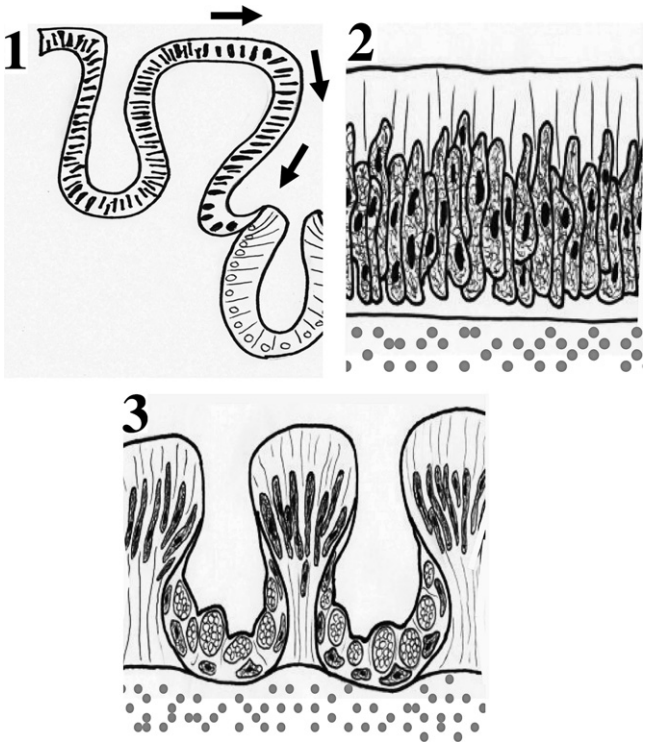

Figure 5. Representation of serrated and adenomatous lesions: (1) adenoma (cell multiplication and growth in the direction of lateral and top-down growth [arrows]), (2) traditional adenoma (elongated and packed nuclei with cellular atypia), and (3) TSA (elongated nuclei, cellular atypia, vertical direction of basal crypts with intraepithelial microacinar insets) (by J. R. Jass).

The pragmatic classification adopted in this article is relevant to the treatment decision planned (no intervention, or endoscopic or surgical resection) and includes 2 modifications of the Vienna classification: (1) the categories ''indefinite'' for noninvasive or invasive neoplasia were withdrawn and (2) the distinction between low-grade or high-grade carcinoma was included. In this situation, low-grade intramucosal neoplasia includes noninvasive (low grade and high grade) intraepithelial neoplasia and low-grade carcinoma. High-grade intramucosal neoplasia corresponds to a high-grade intramucosal carcinoma.

HISTOLOGIC CLASSIFICATION OF SERRATED LESIONS

The term ''serrated'' refers to the histologic appearance of a variety of polyps, the edge of which has a wavy or

TABLE 5. Classification of serrated colorectal lesions*

Serrated lesions: upper crypts (serration), basal crypts (normal proliferation), small basal nuclei	Microvesicular type; predominance of microvesicular cells	Nonneoplastic†
	Goblet-cell–rich type; predominance of goblet cells	
	Mucin-poor type; reduction in mucin in cells	
Serrated lesions: upper crypts (serration), basal crypts (abnormal proliferation), increased mucus	Sessile serrated lesion (often called adenoma); basal crypts; horizontal growth; architectural distortion; elongated nuclei; more mucus; atypia (structural, not cytologic)	
	TSA; basal crypts; vertical growth; neoplasia (structural and cytologic)	Neoplastic
Mixed polyp: mixed parts of HP lesion, classical adenoma	HP and classical adenoma	
	HP and serrated adenoma	

*The term serrated refers to the notched irregular diameter of the crypt lumen. These lesions are nonneoplastic (HP lesions) or neoplastic (serrated adenomas) or a composite with juxtaposition of HP and adenomatous sectors. Sessile serrated lesions are not classified as neoplastic, because there is no cellular atypia in the serrated zone with abnormal architecture.
†Nonneoplastic lesions can theoretically harbor foci of neoplasia; they are considered as neoplasia developed on a nonneoplastic lesion or they belong to the group of mixed polyps.

serrated contour. The specific architectural feature deserving the term ''serrated'' is the irregular and enlarged upper part of the crypts, which are notched like a saw with teeth pointing toward the center of the lumen; the serration index describes the severity of the architectural defect. There is some confusion in the classification of serrated lesions as neoplastic or nonneoplastic, based on whether there is a normal or abnormal proliferation within the crypts. So-called HP polyps have a normal proliferative compartment and very rarely progress to neoplasia. In contrast, traditional serrated adenomas (TSAs) are neoplastic. Sessile serrated lesions appear to be a precursor to cancer with MIS, when they show abnormal proliferation within the crypts. Serrated lesions display a morphology that is similar to that of neoplasia arising from the adenoma-adenocarcinoma sequence[50-74]; however, the surface pattern explored with magnification shows specific characters with enlarged and stellar crypt openings. There is some confusion in their morphologic classification (Figs. 4 and 5, Table 5) as polypoid or nonpolypoid. The terminology HP polyp, which suggests polypoid morphology, is legitimate for unequivocally protruding lesions, which belong to categories 0-Ip or 0-Isp. However, most of the frequently small and <10-mm HP lesions are nonpolypoid and should be classified in the category 0-IIa. Large, sessile serrated lesions located in the right side of the colon adopt a transverse mode of growth, which results in mixed polypoid and nonpolypoid patterns: 0-IIa + IIc or 0-Is + IIa or 0-IIa + IIc, which are often misclassified as LST lesions.

HP polyps

HP polyps are metaplastic, not neoplastic, lesions. They are composed of elongated crypts, with a serrated architecture in the upper half of the crypts, that results in irregular dilatation of the notched lumen.[50,52,54] There is some regular cell proliferation in the basal, nonserrated part of the crypts. Nuclei are small, regular, and basally orientated; there is no stratification in the upper half of the crypts, and both architectural and cytologic features of neoplasia are absent. Three distinct types of cytoplasmic differentiation were described in HP lesions: (1) a microvesicular type, (2) a goblet-cell–rich type, and (3) a mucin-poor type. Practically, it might be very difficult to distinguish these subtypes. The microvesicular type HP lesion may be the precursor of the sessile serrated lesion, whereas the goblet-cell–rich type HP lesion may be the precursor of the TSA. The morphology of HP lesions was described in Japan in a large series ($n = 3060$), in which the majority of lesions were small and located in the distal portion of the colon.[48] As a rule, the risk of progression to neoplasia is negligible for most small lesions located in the distal portion of the colon and rectum, and they may be left without treatment. However, HP lesions larger than 10 mm and those located in the proximal portion of the colon should be resected.

With HP polyposis, the larger and sessile lesions show a high serration index with laterally branching crypts and abnormal cell maturation (mitoses, nuclear changes). In this condition, more than 30 small, or more than 5 large lesions, larger than 1 cm are present in the colon. The large or giant lesions have a sessile morphology and are located in the proximal portion of the colon. HP polyposis is associated with an increased risk of colorectal cancer, evaluated in a series at 54%.[56] Patients with HP polyposis are at high risk for colorectal cancer developed in the proximal portion of the colon.

TSAs

TSAs show neoplastic crypts with a serrated architecture.[57-70] They differ from HP lesions by the complex serrated architecture of the basal part of the crypts, with

TABLE 6. Categories of the pit pattern at the surface of the colonic mucosa*

Histology	Pit pattern†		Treatment selection
Nonneoplastic	Normal mucosa (normal round crypts, regular)	I	No treatment
	HP lesion (enlarged stellar crypts, regular)	II	
Neoplastic, adenomatous	Neoplastic lesion (elongated, sinuous crests)	IIIL	Endoscopic resection

‡Pit pattern V is divided in 2 categories: Vi with an irregular surface and VN, or nonstructural, with an amorphous surface.

elongated nuclei and some stratification in 2 to 3 rows. A BRAF mutation is present in 75% of serrated adenomas.[69] These lesions should be treated in the same way as nonserrated adenomas.

Sessile serrated lesions

Sessile serrated lesions, often called SSAs, differ from traditional adenomas by their flat morphology.[71-73] There is a double ambiguity in their classification under this name. These lesions show no adenomatous changes and should be called ''sessile serrated lesions.'' The term sessile is also confusing, because these lesions often show a nonpolypoid, slightly elevated (0-IIa) morphology rather than a sessile polypoid (0-Is) one.

The frequency of sessile serrated lesions is estimated at about 2% of all colon polyps. However, in a recent study of patients undergoing colonoscopy,[72] the prevalence of sessile serrated lesions was higher (9%). These lesions are associated with the following characteristics: proximal location, female sex, and multiplicity. Architectural features of sessile serrated lesions include the following: (1) an increased serration index in the basal half of crypts, which are dilated, with crypt branching with horizontal growth, and form T-shaped and L-shaped glands just above the muscularis mucosae, (2) an asymmetrical expansion of the proliferation zone into the middle third of crypts, (3) an epithelium-to-stroma ratio often above 50%, (4) an abundant mucus production, with pools of mucin in the lumen of the crypts and on the surface of the mucosa, (5) the presence of slightly enlarged vesicular nuclei with nucleoli. The structural abnormalities that show a complex architecture are compatible with neoplasia, but the cytologic criteria of neoplasia are missing.

The distinction between sessile serrated lesions and serrated adenomas, therefore, mainly depends on cytologic criteria; in addition, Torlakovic et al[73] proposed another difference: the eosinophilic cytoplasm of sessile serrated lesions. Although most sessile serrated lesions will never progress to neoplasia, some, particularly the large sessile serrated lesions in the proximal portion of the colon, progress rapidly to carcinoma[72]; as a rule, those located in the proximal portion of the colon should be resected.

Mixed polyps

Mixed polyps contain distinct sectors that show the architecture of an HP lesion and/or that of a neoplastic serrated lesion.[74] The following mixed patterns have been acknowledged: HP and sessile serrated lesions, HP and TSA, TSA and classical adenoma, sessile serrated lesion and classical adenoma, and TSA and sessile serrated lesion. Mixed polyps should be treated in the same way as TSAs and nonserrated neoplastic lesions.

CLASSIFICATION OF THE SURFACE PATTERN OF NONPOLYPOID LESIONS ON MAGNIFYING ENDOSCOPY

Magnification of the endoscopic image at a power ×80 or more combines optical and electronic technologies and displays the microarchitecture (pits and crests) of the mucosa, which allows classification with clinical relevance for the ''pit pattern.'' Magnification can be coupled with image processing. In the narrow-band imaging (NBI) technique (Olympus Medical Systems Corp, Tokyo, Japan), a special set of filters is interposed on the optical path, and the incident photons are emitted in 2 narrow bands of wavelengths (blue and red). The selective reflection of the NBI light by the superficial layers of the mucosa improves the definition of the surface, and the vessels are highly contrasted in dark brown. Analysis of the disorganized ''vascular pattern'' in the neoplastic mucosa is now a major application of the NBI technique.

TABLE 7. Categories of the pit pattern of superficial neoplastic lesions: exploration conducted in magnification with chromoscopy or NBI

		Pit pattern*				
	Total no. lesions	IIIL	IIIs	IV	Vi‡	VN‡
Polypoid (0-Ip, Ips, Is)	14,084 (61.1%)	10,208	17	3236	511	112
Nonpolypoid (not depressed, 0-IIa, IIb)	8405 (36.4%)	7453	78	551	245	78
Nonpolypoid (depressed, 0-IIc)†	559 (2.4%)	70	257	1	53	178

*Categories of pit patterns in relation to the morphology of 23,048 lesions in the series at the Akita and Yokohama Northern Hospitals during the period April 1985 through July 2007.
†Lesions with a depressed pattern account for 2.4% of all superficial neoplastic lesions (n = 23,048) and for 31.9% of pit pattern types IIIs + Vi + VN.
‡Pit pattern V is divided in 2 categories: Vi, with an irregular surface, and VN, or nonstructural, with an amorphous surface.

TABLE 8. Categories of the vascular pattern at the surface of the colonic mucosa: exploration conducted in magnification with NBI

Histology		Vascular pattern*	Selection of treatment
Nonneoplastic	Normal	Well-delineated capillaries surrounding pits opening	No treatment
	Faint	Poor visibility of capillaries around enlarged pits	No treatment
Neoplastic (tubular, villous adenoma)	Network	Vessels organized in a large and regular mesh	Endoscopic resection
	Dense	Enlarged vessels of regular size at top of elongated epithelial crests	Endoscopic resection
Cancer	Irregular	Enlarged vessels of irregular diameter and diverging directions	Endoscopic resection
	Sparse	Poor distribution of irregular vessels with diverging directions	Surgery

*The 6 categories are classified in reference to prediction of histology and treatment decision.

Classification of the pit pattern

The pit pattern, ie, the microarchitecture of pits, epithelial crests, or ridges, at the surface of the normal or altered colonic mucosa is observed in magnifying endoscopy,[75-77] with the help of chromoscopy by using a 0.2% indigo carmine solution or other dyes. Alternatively, the contrast of the surface is explored without chromoscopy when NBI is coupled with magnification. The progressive alterations of the pit pattern in neoplastic lesions have been confirmed by many investigators since the initial Kudo's classification of the abnormal patterns: (1) in the normal mucosa, the luminal opening of the crypts are round, regular, and narrow, (2) in the nonneoplastic HP lesions, the crypt lumen is large and stellar shaped, (3) in neoplastic lesions, epithelial crests and ridges substitute for this regular honeycomb distribution, and (4) carcinoma is suggested when the surface is irregular, without epithelial crests, or completely amorphous and nonstructural. A grading of the progression of neoplasia in relation to the pit pattern, classified in categories I to VN, has been proposed in Japan (Table 6), and compared with histology in a very large (>23,000) series of superficial neoplastic lesions of the colorectal mucosa (Table 7). The study confirms that depressed nonpolypoid lesions are more advanced than the other lesions, and the pit pattern type V occurs in 41% of them. The proportion of pit pattern V in nondepressed (nonpolypoid or polypoid) lesions is less than 5%. The clinical relevance of the pit pattern for the grading of neoplasia is still debated when 7 categories are used but is well accepted when a simpler classification in 3 categories is used: (1) nonneoplastic (I and II), (2) neoplastic low grade (III), or (3) neoplastic high grade (IV and V).

Classification of the vascular pattern

The vascular pattern at the surface of the digestive mucosa is observed in magnifying endoscopy and in transparency without chromoscopy; the contrast of the vessels is improved when NBI is coupled with magnification. There are still few descriptions of the vascular pattern in the colonic mucosa. For example, in the normal mucosa, well-delineated capillaries surround the opening of the crypts. The endoscopy unit of the Northern Yokohama Hospital analyzed the abnormal aspects according to the following criteria of the capillaries: degree of visibility, enlarged or

TABLE 9. Comparison of the vascular pattern of traditional and serrated adenomas: exploration conducted in magnification with NBI

Vascular pattern*	Adenoma tubular or villous	Serrated adenoma	Total
Faint†	1	14	15
Network	446	8	454
Dense	119	12	131
Irregular	1	0	1
Sparse	0	0	0
Total	567	34	601

*The vascular pattern is analyzed at the surface of tubular or villous adenomas and of serrated adenomas in the series the Yokohama Northern Hospital during the period January 2006 through August 2007.
†Faint pattern that suggests an HP lesion is observed in 41% of serrated adenomas.

irregular diameter, or the absence of symmetry in the direction of capillaries. The abnormal aspects are classified in 5 groups: ''faint,'' ''network,'' ''dense,'' ''irregular,'' and ''sparse.'' In the same endoscopy unit, the vascular pattern at the surface of superficial lesions of the colorectal mucosa was correlated to histology during the period January 2006 through September 2007 (S. Kudo, H. Kashida, unpublished data, 2008). A ''faint'' vascular pattern occurred in 37 of 41 HP lesions and in only 15 of 843 neoplastic lesions. The sensitivity and specificity of the ''faint'' pattern for HP polyps were 98.2% and 90.2%, respectively. A ''nonfaint'' vascular pattern, which regrouped all 4 other abnormal patterns, occurred in 823 of 843 neoplastic lesions and in only 4 of 41 HP lesions. The ''nonfaint'' patterns characterize neoplastic lesions. The classification of the vascular pattern helps in the distinction among nonneoplastic lesions, premalignant neoplastic lesions, and cancer (Table 8), and in the distinction between traditional adenomas and serrated adenomas (Table 9).

GENETIC FACTORS THAT CONTROL THE GROWTH OF TUMORS IN THE COLORECTAL MUCOSA

Considerable progress[78-96] has occurred during the most recent years in the description of genetic events for the adenoma-carcinoma sequence, the HP serrated carcinoma sequence, hereditary cancer,[97-99] and cancer in inflammatory bowel disease.[100-104] A link has been established between the genetic events that control the development of the neoplastic lesions and their morphology (Tables 10 and 11). Colorectal carcinoma develops in 3 distinct genetic pathways: (1) CpG-island methylation phenotype (CIMP), which is classified as high, low, or negative, will inactivate encoding regions of DNA by methylation, (2) CIN, with losses of suppressor genes (APC and TP53) will result in LOH, and mutations with activation of oncogenes (KRAS) 3–MIS, which concerns nonencoding repetitive DNA sequences, is classified as high (MIS-H), low (MIS-L), or stable (MSS). The combination of the 3 pathways results in 5 categories of neoplastic lesions (Table 10), which were classified by Jass.[67] It is estimated that CIN with MSS accounts for around 77% of cases (including the germline mutation of the APC gene), then carcinogenesis is based on the sequence APC-KRAS-TP53. Chromosome stability with MIS results in inactivation of multiple genes; it occurs in close association with BRAF mutation in around 20% of cases or in the germline mutation of a MMR gene (hMLH1).

Genetic factors involved in the development of polypoid carcinoma

Mutations in epithelial cells. In the normal colorectal mucosa, stem cells are thought to reside at the base of crypts; the Fearon and Vogelstein[15] described the progression from the initial subset of neoplastic cells in the ''top-down'' direction, which, in spite of some diverging opinions,[78] is the most accepted theory.[15,79] In line with the top-down theory, the same group[79] compared, in the early stage of an adenoma, the molecular characters of cells with a neoplastic morphology at the luminal surface of the crypts and that of cells with a normal morphology at the base of these same crypts. The cells at the top of the crypts often exhibited genetic alterations that were not observed in cells located at the base of the same crypts. The genetically altered cells arise in the upper pole of the crypt, progress down in the crypt, and spread laterally in adjacent crypts. The growth of neoplastic cells with crypt fission ends in a macroscopic lesion.

The traditional sequence described in 1990 by Fearon and Vogelstein,[15] is responsible for the majority of sporadic colorectal cancer. The mutation of the APC tumor suppressor gene on the long arm of chromosome 5 (5q21) is followed by CIN and LOH, ie, loss of segments of chromosomes, and successive mutations of suppressor genes or activation of oncogenes: K*ras* gene on chromosome 12q, DCC gene on chromosome 18p, and TP53 gene on chromosome 17p (Fig. 6). The repetitive nucleotide sequences of DNA in the microsatellites are not modified by mutations, and the tumor is MSS.

Hirata et al[80] analyzed APC, KRAS, and TP53 gene mutations in 96 cases of primary colorectal cancer and stressed the variable prevalence of associations in altered chromosomes: the combination APC and KRAS occurred in 21.9%; the prevalence of K*ras* and TP53 and of APC and TP53 combinations was 12.5% and 10.4%, respectively; and the combination of APC, K*ras,* and TP53 mutations was the less frequent (6.3%). This variability suggests an interaction between exogenous environmental factors

TABLE 10. Relationship between molecular groups and morphology of neoplastic lesions*

CIMP status	CIN status	MIS status	Inaugural mutation	Related neoplastic lesions	Proportion (%)
High	Stable	MIS-H	BRAF	Serrated lesion; sporadic cancer	12
	Stable	MSS	BRAF	Serrated lesion	8
Low	Unstable	MSS	KRAS	Sporadic adenoma; serrated lesion	20
Negative	Unstable	MSS	KRAS	Sporadic adenoma; FAP; germline mutation	57
	Stable	MIS-H	MLH1	HNPCC; germline mutation	3

MIS-H, High microsatellite instability; *MIS-L,* low microsatellite instability.
*Colorectal carcinoma develops in 3 distinct pathways: (1) CIMP, which is high, low, or negative, (2) chromosomal instability (CIN) with losses of suppressor genes by LOH, (3) microsatellite instability, which is high (MIS-H), low (MIS-L), or stable (MSS); a combination of the 3 pathways results in 5 categories of neoplastic lesions (see reference 67).

TABLE 11. Mutations that occur in neoplastic and nonneoplastic colorectal lesions*

		% Serrated pathway		
Mutation	% Traditional adenoma	HP polyp (microvesicular)	TSA	Sessile serrated lesion
APC	33	0	0	0
KRAS oncogene	15	15	30	7
BRAF protein-kinase	0.3	75	60	80
CIMP	10	50	80	75

*The APC mutation characterizes the adenomatous pathway to cancer. The BRAF mutation characterizes the serrated pathway and is common to HP nonneoplastic polyps and to serrated adenomas (see references 11, 12, 50, 51, 54, 67).

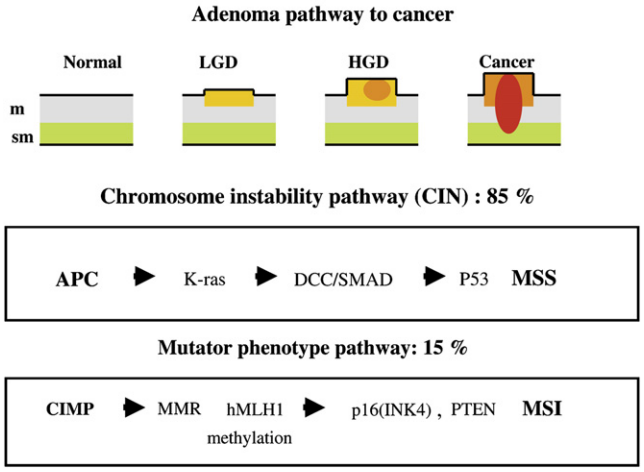

Figure 6. Adenoma pathway to sporadic colorectal cancer. Two distinct sequences monitor the morphologic steps from low-grade neoplasia to invasive cancer. The first is based on initial APC mutation, CIN, and LOH; DNA microsatellites are stable (MSS). The other sequence is based on CIMP, with methylation and inactivation of hMLH1, a MMR gene, which results in MIS and inactivation of many suppressor genes (eg, p16, PTEN). Note: familial cancer, caused by germline mutations, is linked to the APC sequence in the FAP syndrome and to the CIMP sequence in the HNPCC, in which the germline mutation of one of the MMR gene results in high MIS.

and the somatic genetic alterations. Hermsen et al[81] stressed the role of specific associations of mutations in the progression of polypoid adenomas to cancer. They compared chromosome alterations in 66 benign and 46 malignant colorectal adenomas. Three distinct combinations are linked to the progression toward cancer: 17p loss and K*ras* mutation, 8q and 13q gain, and 18q loss and 20q gain.

Genetic instability in epithelial cells. An alternative sequence occurs in up to 20% of cases of sporadic colorectal cancer in relation to the CIMP. Epigenetic methylation and inactivation of hMLH1, one of the MMR genes, results in MIS-H and inactivation of many suppressor genes (p16 and PTEN). The tumors with epigenetic methylation of the DNA are highly correlated with a mutation of the BRAF-kinase encoding gene located on the long arm of chromosome 7 (7q34). This group of MIS tumors offers similarities with neoplastic lesions developed in the serrated pathway, which suggests that the precursor lesion is similar. Kambara et al[94] screened BRAF mutations in different categories of neoplastic colorectal lesions—serrated adenomas, conventional adenomas, and hereditary and sporadic colorectal cancer—and found that BRAF mutation is more frequent in sessile serrated lesions and in sporadic MIS-H cancers, both of which are associated with DNA methylation. Sporadic MIS-H cancers may originate in sessile serrated lesions rather than in conventional adenomas.

Genetic instability in the stroma. Recent studies suggest that, just as for breast cancer, genetic instability in the stroma may influence the progression of neoplastic colorectal lesions. Ishiguro et al[95] analyzed, with microsatellites and chromosome 17 markers, the epithelial and stromal compartments of colorectal adenomas for LOH

and instability in the sequences of microsatellites. In epithelial cells, the prevalence of LOH and MIS, which is extremely low in HP polyps, increases with the progression of the alterations in premalignant adenomas and, furthermore, in invasive carcinoma. In the stroma, the prevalence of LOH or MIS does not vary with the progression of neoplasia. Therefore, genetic instability in the stroma is a very early event in the development of colorectal neoplasia. Matsumoto et al[96] tested MIS with 4 markers in 40 cases of sporadic colorectal cancer: the frequencies of positive MIS in the epithelial and in the stromal compartments were 34% and 41%, respectively. In the epithelial compartment, positive MIS is more frequent in poorly differentiated than in well-differentiated cancer. In the stromal compartment, an opposite variation occurs: positive MIS is more frequent (54%) in well-differentiated cancer (54%) than in poorly differentiated cancers (10%). It is concluded that, rather than being a reaction to epithelial tumoral cells, stromal genetic instability in chromosome 17 markers may control the development and differentiation of the tumor.

Genetic factors involved in the development of nonpolypoid or flat carcinoma

The distinct sequence of genetic events that controls the development of nonpolypoid lesions in the colorectal mucosa is progressively being confirmed with techniques that vary from immunochemistry in tissue sections to microdissection and DNA sequencing.[47,81-89,92] Molecular events that occur in nonpolypoid lesions were analyzed in 3 distinct circumstances: (1) flat adenomas, classified as premalignant lesions, either when including all depressed and nondepressed subtypes or when including only the flat depressed adenomas, (2) LST lesions, which were classified with ambiguity in granular, nongranular, and homogenous subtypes, rather than in subtypes of the Paris classification, (3) flat carcinomas or, more precisely, flat carcinomas that show no remnants of adenoma, which are often called de novo cancer. The heterogeneity of early neoplastic lesions in patients with inflammatory bowel disease is beyond the scope of this discussion, in spite of the unusual high proportion of neoplastic areas with a flat morphology.[100-104]

Mutations in epithelial cells. In flat adenomas, K*ras* mutations have a lower frequency in flat nonpolypoid lesions than in polypoid lesions, as shown by Yamagata et al[87]; the figures in their study were 23% and 67%, respectively. More precisely, the frequency of K*ras* mutations in depressed adenomas and in polypoid adenomas were estimated in 2 other studies: the figures were at 0% and 31%, respectively, in the study by Umetani et al[89] and at 8.6% and 25%, respectively, in the study by Morita et al,[82] restricted to diminutive lesions less than 5 mm in diameter. The frequency of APC mutations has also been estimated in depressed lesions and is lower (7%) in nonpolypoid depressed adenomas than in polypoid lesions (43%), as shown by Umetani et al[89] in 2000.

In LST lesions, Mukawa et al[85] compared the frequency of K*ras* mutations in subtypes of LST lesions and found a lower prevalence of the mutation (26.3%) in 19 cases with a nongranular type (which is usually flat) than in 17 cases with a granular type (76.5%). This was confirmed by Hiraoka et al,[84] who compared K*ras* mutations in LST lesions at least 1 cm in diameter: the prevalence of the mutation was lower (16%) in the flat type with a homogenous surface, than in the more protruding granular type (78%). Takahashi et al[83] obtained different results when comparing K*ras* mutations in 101 LST lesions, called flat advanced adenomas, and in 68 polypoid advanced adenomas: the prevalence of K*ras* mutations was higher (35%) in LST lesions than in polypoid adenomas (13%). The divergence in the results of these studies may relate to the imprecision in the morphologic classification of LST lesions.

In flat carcinomas (1) in various studies that compared flat carcinomas with polypoid carcinomas, the low frequency of K*ras* mutations is confirmed: the published figures were 11% and 56%,[89] 0% and 44%,[88] and 0% and 36%,[47] respectively, (2) frame-shift mutations of the APC gene do not occur in nonpolypoid carcinomas and occur in 66% of polypoid carcinomas, as shown by Kaneko et al,[47] (3) mutations of the TP53 gene were analyzed by Fujii et al[91] in 13 cases of early flat cancer: LOH on chromosome 17p locus, near the TP53 gene occurs early and is frequent (77%), genetic heterogeneity is similar to that observed in more advanced polypoid cancer in the preinvasive stages. The prevalence of TP53 mutations in early and flat cancer was also analyzed in European series.[90-93] Mueller et al[90] compared the frequencies of LOH at the 17p locus near the TP53 gene in 35 cases of early colorectal cancer without residual adenoma (de novo cancer) and in 36 cases of superficial (pT1) cancer developed in the adenoma sequence: the prevalences were 73% and 37%, respectively. In conclusion, the more aggressive character of the de novo carcinoma is confirmed by the higher rate of LOH at 17p locus with more frequent TP53 mutations.

Genetic instability in epithelial cells and stroma. In advanced carcinomas,[47] nonpolypoid and polypoid tumors show a similar proportion of MIS. In 99 superficial (early) colorectal carcinomas with invasion of the submucosa, Ogawa et al[34] analyzed genetic instability with microsatellite markers from the National Cancer Institute and for chromosome 17 instability. The frequency of epithelial MIS is significantly higher in nonpolypoid (33.3%) than in polypoid superficial cancer (10.4%). In the stroma of the tumor, instability of chromosome 17 markers is higher in nonpolypoid than in polypoid superficial cancers. It is concluded that epithelial and stromal MIS of chromosome 17 markers contributes more to carcinogenesis in nonpolypoid lesions.

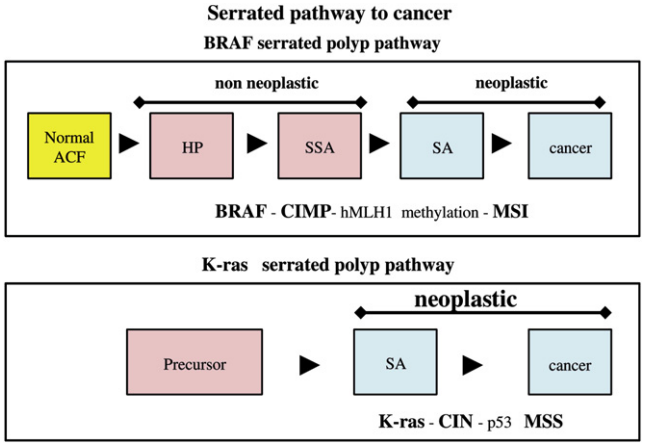

Figure 7. Serrated pathway to sporadic colorectal cancer. Two distinct molecular sequences monitor the morphologic steps from nonneoplastic lesions to neoplasia and invasive cancer. Serration is included in both sequences. The first is based on initial BRAF mutation and CIMP, with inactivation of hMLH1, which results in MIS. The HP lesion, eventually arises from ACF and is not neoplastic; a sessile serrated lesion is often called sessile serrated adenoma as well; serrated adenoma (SA) is a neoplastic lesion and may progress to cancer. The other sequence, based on early K-ras mutation and CIN, results in a serrated adenoma (SA) which may progress to cancer; the DNA microsatellites are stable (MSS).

Combined chromosomal alterations in flat carcinomas. K*ras* and APC mutations are less frequent in nonpolypoid than in polypoid lesions. The difference was confirmed in various categories of lesions: flat adenomas, depressed flat adenomas, nongranular type of LST lesions, flat carcinomas, and de novo carcinomas. In the majority of studies, flat lesions are considered as a single group, and a specific behavior of depressed lesions is not underlined. Also, chromosomal alterations may be combined to convey a more aggressive behavior of the tumor. The simultaneous and early occurrence of multiple LOH, including 17p, 18p, 18q, and 22q in colorectal flat tumors suggests their classification as a de novo cancer with more aggressive clinical behavior.[35] In the Netherlands, Postma et al[86] analyzed 6 flat adenomas and 12 flat adenocarcinomas, and found higher frequencies of 20q gain and 18q loss than in previously analyzed polypoid neoplastic lesions. Combined alterations in these 2 chromosomal regions were already linked to tumor aggressiveness by the same group.[81] Epithelial MIS is more frequent in nonpolypoid lesions.

Genetic factors involved in hereditary cancer

Hereditary cancer syndromes are caused by germline mutations. In familial adenomatous polyposis (FAP), the colorectal tumor shows MSS and is caused by a dominant germline mutation in the APC gene on chromosome 5q; a clinical syndrome of attenuated FAP is caused by a mutation of a BER (base excision gene, located on chromosome 1p. In the hereditary nonpolyposis colon cancer (HNPCC) syndrome, the tumor with MIS is caused by a dominant germline mutation of one of the MMR genes, which results in high instability of the repeated sequences of nucleotides in MIS-H and multiple mutations of suppressor genes in the CIMP phenotype.[97-99]

Genetic factors involved in the development of serrated lesions

Mutations with MIS. Serrated lesions cover a spectrum of nonneoplastic and neoplastic lesions and share a persisting serrated pattern of the crypts. The majority of serrated neoplastic lesions show MIS with a MIS-H status. Mutation of the BRAF-kinase gene on chromosome 7q (Fig. 7) and DNA epigenetic methylation are early events in this pathway to neoplasia, and the frequency of this mutation in colorectal polypoid lesions has often been analyzed.[69,72,94] The methylator phenotype is absent in simple HP lesions and frequent in HP polyposis; the prevalence of this phenotype progressively increases in the continuum that leads to a serrated carcinoma. After the initial BRAF mutation, the molecular events include inactivation through methylation of the MMR gene hMLH1, with MIS-H and successive mutations of suppressor genes. Spring et al[72] explored the frequency of BRAF mutations in different categories of lesions detected in patients who had colonoscopy: the mutation, rare in adenomas (0.4%), was frequent in the microvesicular type of HP lesion (70%), in sessile serrated lesions (78%), and in TSAs (66%). Kambara et al[94] analyzed BRAF mutations in patients undergoing colectomy for either colorectal cancer or HP polyposis; a high prevalence was confirmed in sessile serrated lesions and in sporadic colorectal cancer with a MIS-H status. The microvesicular type of the HP lesion is considered the precursor of sessile serrated lesions, which can progress to neoplasia but should not be misclassified as a TSA, which is a neoplastic lesion. Torlakovic et al[73] showed that the distribution of cells labeled with Ki-67 is the most helpful feature for the distinction between the 2 categories of lesions: the expression of Ki-67 is irregular and highly variable in sessile serrated lesions and is localized in the ectopic crypts, which characterize the architecture of TSAs. Most likely, sporadic MIS-H cancers originate from sessile serrated lesions as a consequence of the CIMP, which leads to successive mutations of suppressor genes.

Mutations with MSS. An alternative sequence that leads to a serrated carcinoma is based on an initial K*ras* mutation with CIN. Successive mutations of suppressor genes result in a TSA that may progress to a serrated cancer; the DNA microsatellites are MSS in this category of tumor.

ROLE OF ABERRANT CRYPT FOCI ON THE ORIGIN OF COLORECTAL CARCINOMA

Aberrant crypt foci (ACF) are defined as small clusters (2 or more) of enlarged crypts with dilated openings,

which rise above the adjacent mucosa.[105-114] ACF can be identified and numbered at the surface of the mucosa with magnification chromoendoscopy, by using indigo carmine solution at 0.2%, or methylene blue solution at 0.01%. The numeration is usually performed with a high-power field, which may vary according to the material used and the investigators, in a 20-cm or 10-cm length of the rectum. The count increases with the age of the patient, just as the risk of colorectal cancer increases.[112] The ACF count is not temporally stable, as shown in a study by Schoen et al,[114] who identified and counted ACF again, after a 1-year interval, in the rectum: less than half the specific ACF could be reidentified, and more than 50% of the subjects had new ACF. ACF are postulated to represent the monocryptal initial event in the development of neoplastic lesions or serrated lesions in the colorectal mucosa.

Diversity of ACF phenotypes

ACF are classified into 3 categories: (1) HP ACF have a nonserrated morphology, the crypt lumen is round but enlarged, and the mucin content is not increased, (2) HP serrated ACF show a serrated crypt lumen with increased mucin, and (3) neoplastic ACF are less frequent and show enlarged and stratified nuclei. ACF with a neoplastic type can be considered a microadenoma and can have proliferation in the upper part of the crypt, and are more common in FAP than in patients with sporadic colorectal neoplasia. In contrast, the nonneoplastic categories of ACF (called heteroplastic) have proliferation mainly in the lower part of the crypts.

Diversity of ACF genotypes

The distinct sequences that lead to neoplasia across the nonserrated and serrated pathways have been studied after direct polymerase chain reaction (PCR) sequencing of the DNA from isolated ACF with an HP, serrated, or neoplastic architecture. BRAF mutations are linked to HP ACF with a serrated phenotype, and K*ras* mutations are linked to ACF with a nonserrated phenotype. In the study conducted by Rosenberg et al,[110] BRAF mutation was present in 10 of 16 serrated ACF and in only 1 of 33 nonserrated ACF; conversely, K*ras* mutation was present in 3 of 16 serrated ACF and in 14 of 33 nonserrated ACF. Beach et al[69] confirmed that BRAF mutation was rare in nonserrated neoplasia, did not occur in ACF from patients with hereditary cancer (FAP), and only occurred in 3% of ACF from patients with sporadic colorectal cancers. K*ras* mutation was present in only 4% of ACF from patients with hereditary cancer (FAP) and occurred in 40% of ACF from patients with sporadic colorectal cancers.

ACF and the risk of cancer

The count of ACF in the rectum follows a stepwise progression in patients with a negative colonoscopy, adenomatous polyps, or colorectal cancer, and in the study conducted by Adler et al,[105] the values of the count of ACF in these 3 categories were n = 5, n = 6.9, and n = 9.9, respectively, and in the study conducted by Takayama et al,[109] the figures were n = 1, n = 5, and n = 26.5, respectively. Kukitsu et al[111] showed that the number of ACF is higher in patients with ulcerative colitis when a neoplastic lesion is associated. The relationship between the prevalence of ACF in the rectum and the presence of nonpolypoid neoplastic lesions in the proximal portion of the colon was also analyzed. In the study conducted by Hurlstone et al,[106] the mean number of ACF in the rectum was n = 1 in patients with a negative colonoscopy, n = 9 in those with nonpolypoid adenomas, and n = 38 in those with a nonpolypoid cancer in the proximal portion of the colon.

In hereditary cancer, Nucci et al[113] showed that most ACF in patients with a FAP syndrome have a neoplastic morphology, whereas those observed in patients with sporadic colorectal cancer have an HP morphology. In the study conducted by Beach et al,[69] 91% of ACF from patients with a FAP syndrome had a neoplastic morphology, whereas 87% of ACF from patients with sporadic colorectal cancer were HP. Stevens et al[108] established a relationship between the count of ACF and the familial risk of cancer. The count was lower (n = 4.4) in patients without a family history of cancer than in patients with a family history of cancer (n = 9) or with a personal history of cancer (n = 7.5).

In conclusion, ACF are considered as the earliest and monocryptal precursors of neoplastic lesions in the colon and are postulated as valuable biomarkers for the risk of colorectal cancer. They could prove helpful in surveillance protocols of patients at increased risk of cancer, including those with inflammatory bowel disease. In addition, genetic alterations in ACF differ in the serrated and nonserrated neoplasia.

ENDOSCOPIC FEATURES OF NONPOLYPOID LESIONS

Endoscopic prevalence of superficial neoplastic lesions

The prevalence of superficial lesions detected during complete colonoscopy in the colorectal mucosa of asymptomatic patients is high in Japan.[115,116] In a study conducted at the National Cancer Center in Tokyo in 2004 by the Research Cancer Center for Prevention and Screening,[116] the prevalence of neoplastic lesions was 60% in 2968 patients. In Western countries, the figures depend on the recourse to high-resolution endoscopy and image processing during colonoscopy. In the United States, Imperiale et al[117] proceeded to colonoscopic screening in 906 patients: the percentage of patients with adenoma was 10%. A higher proportion (37.5%) was found in 3121 patients by Lieberman et al,[118] and

TABLE 12. Superficial neoplastic colorectal lesions and numbers and proportion of depressed nonpolypoid types: comparison between Japanese and Western series*

Study	No. all lesions	No. flat and depressed lesions (0-IIc, 0-IIc + IIa, 0-IIa + IIc) (%)
Okuno et al,[124] multicenter study (8 groups), Japan	66,670	1291 (1.9)
Togashi et al,[125] Japan	5408	152 (2.8)
National Cancer Center, 2004, Tokyo, Japan	4303	31 (0.7)
Fujii et al,[130] U.K.	68	2 (2.)
Rembacken et al,[132] U.K.	446	4 (0.9)
Hurlstone et al,[131] U.K.	745	51 (6.8)
Kiesslich et al,[5] Germany	105	2 (2)
Tsuda et al,[133] Sweden	973	14 (1.4)
Soetikno et al,[137] U.S.	1535	18 (1.2)

*The proportion of depressed (0-IIc) lesions that occur in the Western series is similar to that observed in the Japanese series. Misclassification between some subtypes (0-Is vs 0-IIa and 0-IIb vs 0-IIa) may occur in the Western series. In all series, lesions with intramucosal or submucosal cancer are included; cancer with invasion beyond submucosa is not included.

even higher figures (67%) were displayed by Rex and Helbig[119] in a recent cohort of 434 patients aged 50 years or older.

Follow-up studies give an indication about the natural evolution of polypoid adenomas that were not removed after detection. In Denmark, a prospective follow-up study was conducted over 3 years in 58 patients undergoing annual colonoscopy, whereas all polyps smaller than 10 mm were maintained.[120-122] In this study, adenomas and HP polyps smaller than 5 mm showed a tendency to net growth, whereas lesions in the size range 5 to 9 mm showed a tendency to net regression.[120-122] In the United States, the ''observed'' incidence of adenomas and colorectal cancers that occurred in the National Polyp Study during surveillance procedures was compared with the simulated outcomes of a MISCAN-COLON model.[123] The discordance between the high incidence of adenomas detected and the low incidence of colorectal cancer suggest that the rise of new adenomas is accompanied by the regression of many others.

Proportions of polypoid and nonpolypoid lesions

In Japan, the proportions of polypoid and nonpolypoid superficial lesions of the colorectal mucosa were estimated in very large series[124,125] collected during a prolonged period (15-20 years). In the endoscopy units from the Akita and Yokohama hospitals (1985-2007), the proportion of nonpolypoid lesions was high, with 10,948 nonpolypoid lesions (42%) of 25,862 superficial neoplastic lesions detected. In a similar analysis from the endoscopy unit of the Hiroshima University Hospital (1991-2007), the proportion of nonpolypoid lesions was still high, with 2711 nonpolypoid lesions (27%) of 12,811 superficial neoplastic lesions detected.

In Western countries, the finding of flat or depressed nonpolypoid neoplastic lesions in the population was acknowledged in recent years,[126-130] and the proportions of polypoid and nonpolypoid lesions were also analyzed or reviewed in some studies.[131-137] In the United States, O'Brien et al[26] revised the classification of data in the National Polyp Study and estimated the proportion of nonpolypoid lesions at 31.4%. In the recent study of Soetikno et al,[137] the overall prevalence of nonpolypoid neoplastic lesions was 9.35%; in this series, nonpolypoid neoplastic lesions, irrespective of their size, were more likely to contain carcinoma than polypoid lesions. Saitoh et al[135] detected, with dye-assisted colonoscopy, flat and depressed lesions in 22.7% of 211 patients; depressed lesions were also more likely to show invasive cancer (4.5%) than were polypoid lesions (0%). Lieberman et al[134] analyzed the yield of recurrent neoplastic lesions that occurred after an interval of 5.5 years but did not describe the morphology of the lesions. In Europe, the proportions of nonpolypoid lesions were estimated at 27.3% by Rembacken et al,[132] 40.9% by Hurlstone et al,[131] and only at 8.4% by Tsuda et al.[133]

Endoscopic prevalence of depressed nonpolypoid lesions

The attention is drawn, in spite of their relative rarity, on depressed lesions (0-IIc, 0-IIc + IIa, or 0-IIa + IIc), because, even when small, they are more advanced in their progression to cancer. In published data from Japan and from Western countries, these lesions represent 1% to 6% of the total count of superficial colorectal lesions, as shown in various series (Table 12). In Japan and, specifically, in the large series from the Akita and Yokohama Hospitals, all subtypes of premalignant and malignant depressed lesions (0-IIc, 0-IIc + IIa, and 0-IIa + IIc) represent 2.3% of all superficial lesions (polypoid and nonpolypoid) and 5.5% of all nonpolypoid types (585 of 10,948) (Table 13). The proportions for the series of the Hiroshima University Hospital are 2.2% of all lesions and 10.5% of nonpolypoid lesions (285 of 2711) (Table 14).

The relative rarity of depressed lesions is still confirmed when the count is restricted to early cancer. In the statistics of the national cancer screening in Japan (2004-2005), 0-IIc lesions represent 8.7% (367/4180) of all cases of early cancer (Table 15); the lesions were detected in patients positive for the immunologic fecal blood test. The

TABLE 13. Morphology of superficial neoplastic lesions and the proportion of Ca in the submucosa: results in 25,762 lesions from the series of the endoscopy unit at Akita and Yokohama Northern Hospitals, Japan, for the period April 1985 through July 2007*

	No. lesions				
	Total	Up to 5 mm	6–10 mm	11-19 mm	≥20 mm
Polypoid, 0-I, Ips, Is					
No. all lesions	14,814	7046	5582	1863	323

No. submucosal Ca only (%)	77 (27)	6 (6)	17 (17.7)	34 (53.4)	20 (80.0)
Total superficial neoplastic lesions	12,811	6996	3448	1730	637

*Proportions of polypoid, nonpolypoid not depressed, and polypoid depressed lesions are 78.8%, 18.9%, 2.2%, respectively. Submucosal invasion occurs in 510 lesions, of which 256 are nonpolypoid. The number of nonpolypoid and depressed lesions is small, but the proportion of cancer with submucosal invasion is high.
†LST lesions type LST-granular (n = 510) are not included; pseudodepressed lesions type LST-nongranular are included in nonpolypoid depressed lesions.

proportion is slightly higher in the study conducted at Jichi University, where 0-IIc lesions represent 10.4% of all cases of early cancer (39/373) (Table 16).

Distribution of subtypes in LST lesions

In Japan, the distribution of the morphologic subtypes of 1751 lesions classified as LST, is shown in a cumulative analysis of the experience of the endoscopy units of Akita and Yokohama Hospitals and of the National Cancer Center in Tokyo (S. Kudo, T. Fujii, unpublished data, 2008): 889 LST lesions were classified as granular, and 862 LST lesions were classified as nongranular. The sizes of the lesions were less than 20 mm in 1144 and 20 mm or greater in 607 (Table 17). In the recent experience at the

Excavated	III	9	2 (22.2)

Ca, Cancer.
*Total number of superficial Ca m or sm detected and classified in subtypes 0 is 4180. Total number of Ca sm is 1096. The proportion of submucosal invasion is much higher in the 2 groups of type 0-IIc lesions.

Yokohama Hospital (S. Kudo, H. Kashida, unpublished data, 2008) of 699 LST lesions (Table 18), the proportion of LST lesions with a nongranular and pseudodepressed morphology is 9.8% (69/699). This subtype of LST lesion corresponds to a more advanced stage in the progression to cancer. When compared with polypoid neoplastic lesions, LST lesions were characterized by different molecular markers.[83,138,139]

Proportions of adenomatous and serrated lesions

In Japan, the size and location in the colon and rectum of HP lesions were analyzed in the National Cancer Center Hospital East, Chiba,[55] in 226 patients who harbored such lesions at colonoscopy: the majority of HP lesions (3020/3060) were less than 6 mm in diameter and were located in the distal portion of the colon (95%); only 5% of these lesion were in the proximal portion of the colon. In this series, which excluded patients with HP polyposis, mid-sized HP lesions (6-10 mm) were rare (28/3060) and were located either in the distal portion (58%) or in the proximal portion (42%) of the colon, whereas lesions 10 mm and larger were extremely rare (2/3060) and were located in the proximal portion of the colon.

In the United States, a multicenter study assessed the proportions of adenomatous and serrated lesions during colonoscopies performed in the Minnesota Community Practice study during the period February 1 through December 31, 2007 (J. Allen, unpublished data, 2008). Among 15,015 lesions detected, 8897 were classified as adenomatous (58%) and 5229 were serrated (37%) (the others were not analyzable with precision). Among adenomatous lesions, 1413 corresponded to advanced neoplasia (19.1%) (tubular adenoma at least 10 mm, villous adenoma, HGIN, or cancer). Among serrated lesions, 3742 were classified as HP, and 1688 were classified as sessile serrated lesions.

A similar study was conducted by Spring et al[72] in 414 superficial lesions detected during colonoscopies at the Royal Brisbane Hospital, Australia. The proportions of adenomatous and serrated lesions were 60% and 40%, respectively. Of the 248 adenomatous lesions, 237 were found to be tubular and 11 tubulovillous. Among 166 serrated lesions, there were 120 HP, 36 sessile serrated lesions, 3 mixed polyps, and 7 TSAs.

ENDOSCOPIC FEATURES OF MALIGNANT NONPOLYPOID LESIONS

Cancer in polypoid and nonpolypoid lesions

The proportion of cancer with invasion of submucosa was analyzed in relation to morphology in endoscopic series from Japan. At the Akita and Yokohama Northern Hospitals (Table 13), the proportion of cancers with invasion of the submucosa was very high in depressed nonpolypoid lesions: 35.9% (210 of 585 lesions). In the series of the Hiroshima University Hospital (Table 14), the figure was also very high for the same category of lesions: 27% (77 of 285 lesions). In contrast, in both series, the proportions of cancer with invasion of the submucosa were very low in polypoid lesions: 2.4% and 0.7%, respectively. In the statistics of the national cancer screening in Japan for the period 2004 to 2005, the proportion of cancer with invasion of the submucosa in depressed nonpolypoid lesions with early cancer was also high and was estimated at 64% (Table 15). A study of the depth of invasion in the submucosa was conducted at the pathology department of the National Cancer Center, Tokyo, Japan, (T. Shimoda, unpublished data, 2008) in 146 superficial colorectal cancers with submucosal invasion. The analysis included polypoid and nonpolypoid early cancers. The depth of invasion was estimated from the muscularis mucosae and was classified as sm1, if invasion was less than 1000 μm, and sm2, if invasion was more than 1000 μm.

In 87 polypoid carcinomas, sm1 invasion occurred in 52.9%, and the average size of sm1 tumors was 21.5 mm; sm2 invasion occurred in 47.1%, and the average size of sm2 tumors was 27.7 mm. In 59 nonpolypoid carcinomas, sm1 invasion of the submucosa occurred in 27.1%, and the average size of sm1 tumors was 12.2 mm; sm2 invasion occurred in 72.9%, and the average size of the tumor was 14.8 mm. It was concluded that nonpolypoid lesions with invasion of the submucosa show a higher proportion of massive invasion and are smaller than polypoid lesions. In Western countries, the proportion of cancer (without distinction between intramucosal or submucosal invasion) was analyzed in relation to morphology and was also high for depressed lesions, and varied from 11.7% to 50% in several endoscopic series. In contrast, the

Tokyo	232	25 (11)	19	8 (42)

Ca, Cancer.
*The risk of cancer with submucosal invasion increases with the size of the lesion.

proportion of cancer in polypoid lesions was very low and varied from 0.6% to 1.2% (Table 16).

Cancer in LST lesions

The risk of cancer in LST lesions increases with size and varies with morphologic subtypes. At the Akita and Yokohama Hospitals during the period from April 1985 to July 2007 (S. Kudo, H. Kashida, unpublished data, 2008), 1209 LST lesions were distributed according to their size in 3 groups: 10 to 19 mm, 20 to 29 mm, and 30 mm and larger; the proportions of cancer with invasion of the submucosa were 4.4%, 13.1%, and 20.6%, respectively. The risk of cancer varied with the subtype of the LST lesion and was higher in the granular with mixed nodules and in the nongranular and pseudodepressed subtypes. In 181 lesions of the subtype granular with mixed nodules, the proportions of cancer with submucosal invasion in the 3 groups of increasing size, 10 to 19 mm, 20 to 29 mm, and 30 mm and larger, were 7.1%, 20.4%, and 38.0%, respectively, and, in 123 lesions of the subtype nongranular and pseudodepressed, the figures were 12.5%, 32.4%, and 83.3%, respectively.

Cancer in serrated lesions

The malignant potential of serrated adenomas is lower than that of traditional adenomas. A study conducted by Song et al[60] in Korea compared 124 serrated adenomas with serration of 20% of crypts and cytologic alterations of nuclei with 419 traditional adenomas. The incidence of HGIN or carcinoma was lower (3.2%) in serrated adenomas than in traditional adenomas (9.3%). Although most sessile serrated lesions never progress to cancer, some of them with a large diameter in the proximal portion of the colon may progress rapidly to a serrated carcinoma.[71] Large lesions in the proximal portion of the colon with a preponderant nonpolypoid pattern at endoscopy deserve special attention with respect to the early detection of serrated cancer and its precursors. The broad categories of large lesions located at this level include sessile serrated lesions, as well as precursors of nonserrated cancer, such as flat or slightly elevated adenomas and LST lesions.

The proportions of serrated and nonserrated cancer can be evaluated because colorectal cancer, developed in a serrated lesion, shows some distinct characteristics in addition to specific genetic markers and some MIS.

TABLE 18. Predictive value of the morphology of LST of neoplastic lesions for Ca in the submucosa: results of 699 lesions from the Yokohama Hospital during the period April 2001 through July 2007*

			No. lesion (% submucosal)		
	Subtype of LST	Total no.	10-19 mm	20-29 mm	≥30 mm
Granular type	Homogenous	251	0/120 (0)	1/65 (1.5)	0/66 (0)
	Nodular mixed	81	2/16 (12.5)	4/24 (16.7)	13/41 (31.7)
Nongranular type	Elevated	298	13/203 (6.4)	7/67 (10. 4)	8/28 (28.6)
	Pseudodepressed	69	10/36 (27.8)	12/29 (41.4)	4/4 (100)

Ca, Cancer.
*Ca with submucosal invasion occurs rarely in the granular homogenous type and is frequent in the nongranular pseudodepressed type.

TABLE 19. Predictive value of the pit pattern for Ca in the submucosa—exploration conducted in magnification with chromoscopy or NBI: no. Ca with submucosal invasion in relation to pit pattern of 7749 colorectal lesions in the series at the Yokohama Northern Hospital during the period between April 2001 and July 2007*

		No. adenoma		
Pit pattern	No. total	Low-grade IEN	High-grade IEN	No. Ca sm
IIIL	5519	5228	291	0
IIIs	73	56	15	2
IV	1577	1190	343	44
Vi (irregular)	463	109	198	156
VN (amorphous)	117	0	10	107

Ca, Cancer; *IEN,* intraepithelial neoplasia.
*Adenoma is classified in low-grade IEN and high-grade IEN (of the Vienna classification); mucosal Ca is included in high-grade IEN; high-grade adenoma includes intramucosal Ca. Most adenomas show a pit pattern type III or IV, most Ca show a pit pattern type V.

These criteria[57] include a persisting serrated growth pattern, pools of mucin, cytoplasmic eosinophilia, and an absence of necrosis.[57] Serrated adenocarcinoma accounts for about 7.5% of all colorectal cancers and up to 17.5% of the most proximal cancers.[57] The proportion of serrated cancer is higher in the proximal portion of the colon and lower in the rectum.

MAGNIFYING ENDOSCOPY IN MALIGNANT NONPOLYPOID LESIONS WITH SUBMUCOSAL INVASION

Evaluation of submucosal invasion from the superficial pit pattern

The pit pattern of the colonic mucosa can be assessed by using magnifying endoscopy in conjunction with chromoscopy or NBI. The studies conducted by various endoscopy groups in Japan, with histologic controls, confirmed that some categories of the pit pattern are predictive of cancer extension into the submucosa. In 7740 neoplastic colorectal lesions analyzed at the Northern Yokohama Hospital (Table 19), submucosal cancer was confirmed by histology in 33.7% of lesions that showed a category V ''irregular'' pit pattern and in 91% of the lesions that showed an ''amorphous'' category V pit pattern, whereas the proportion in lesions that showed pit patterns III or IV was extremely low (0.64%). Furthermore, the ''irregular'' or ''amorphous'' subtypes of the pit pattern in category V showed a predictive value for the slight or massive invasion in the submucosa, as shown in Table 20. The slight or massive submucosal invasion is classified in reference to 3 successive levels (sm1, sm2, and sm3) in vertical extension and to 3 successive degrees of transversal extension of the cancer, estimated just below the level of the muscularis mucosae (sm1a, sm1b, and sm1c). Slight invasion of submucosa corresponds to sm1a or sm1b. Massive invasion corresponds to sm1c, sm2, and sm3. The pit pattern V ''amorphous'' always corresponds to a massive invasion of the submucosa in the experience at the Northern Yokohama Hospital.

Evaluation of submucosal invasion from the superficial vascular pattern

The vascular pattern of the colonic mucosa can be assessed by using magnifying endoscopy with NBI and has a predictive value for the detection of cancer. The vascular pattern at the surface of 843 superficial neoplastic lesions of the colon was analyzed in the endoscopy unit at the Yokohama Northern Hospital. The ''irregular'' or ''sparse'' patterns were found in only 1 of 639 adenomas or serrated adenomas, in 22 of 133 intramucosal cancers, and in 59 of 71 cancers with submucosal invasion (Table 21). The reliability of the vascular pattern in predicting the depth of invasion of the submucosa was explored by the same group during the period from January 2006 to September 2007 (S. Kudo, H. Kashida, unpublished observations, 2008)

TABLE 20. Predictive value of the pit pattern for the depth of submucosal invasion in superficial Ca: depth of invasion in 178 colorectal lesions that showed a surface pit pattern Vi or VN in the series from the Akita and Yokohama Northern Hospitals during the period April 1992 through July 2007

		Ca with submucosal invasion	
Pit pattern V	Total no.	Slight	Massive*
Pattern type Vi irregular histology (low-grade IEN)†	35	29	6 (17%)
Pattern type Vi irregular histology (high-grade IEN)†	80	12	68 (85%)
Pattern type VN (amorphous)	63	0	63 (100%)

Ca, Cancer; *IEN,* intraepithelial neoplasia.
*Massive invasion shows either a pit pattern VN or Vi.
†Pit pattern type Vi is highly suggestive of a superficial invasion of the submucosa.

Sparse†	0	5	32
Total	639	133	71

*Suggests adenoma.
†Suggests carcinoma with submucosal invasion.

in 204 superficial neoplastic lesions with histologic controls. The invasion was classified as slight or massive, with the criteria already used for the evaluation of the pit pattern. The patterns ''network'' or ''dense'' were observed in 123 lesions, of which 120 had a slight invasion of the submucosa and 3 had massive invasion. The patterns ''irregular'' or ''sparse'' were observed in 81 lesions, of which 28 had slight invasion and 53 had massive invasion. The sensitivity and specificity of ''irregular + sparse'' patterns for massive submucosal invasion were 94.6% and 81.1%, respectively. It was concluded that the pit pattern has a high predictive value for a massive invasion of the submucosa.

PROTECTION AFFORDED BY COLONOSCOPY AGAINST COLORECTAL CANCER

The role of colonoscopy in the prevention of colorectal cancer depends on its double function: first, in the diagnosis of cancer at an early curable stage and for the diagnosis of the precursors of cancer—this occurs in opportunistic screening of asymptomatic patients and in organized screening after a positive fecal occult blood test; second, as a therapeutic procedure that allows the endoscopic resection of precursors of cancer and of superficial cancers without massive invasion of the submucosa. The degree of protection afforded by colonoscopy can be explored in patients in whom the initial colonoscopy was negative or in patients in whom the index procedure detected and removed neoplastic lesions. This raises the question of the interval to be proposed for surveillance colonoscopy.

Protection after a negative colonoscopy

Evaluation of the miss rate in back-to-back colonoscopy. Neoplastic lesions detected a few years after a negative colonoscopy may result from a missed diagnosis, ie, false negative for neoplasia. The magnitude of such a miss rate has been determined in Western countries when a second procedure is performed on the same day (back-to-back colonoscopy) by another observer. In a demonstrative study conducted by Rex et al[140] in the United States, the tandem procedure detected adenomas in 24% of 183 patients who had a negative colonoscopy at the initial procedure. The rate varied with the size of the missed adenomas and the figures were 27% for adenomas up to 5 mm, 13% for adenomas between 6 and 9 mm, and 6% for adenomas 10 mm or larger. One may think that this proportion should decrease with the use of recent high-resolution endoscopes. However, in a recent study of back-to-back colonoscopies in 286 patients conducted in France by Heresbach et al,[141] the global miss rate was still high (20%), with proportions of 26% for adenomas up to 5 mm and 9% for adenomas larger than 5 mm. Regardless, when the colorectal mucosa was systematically scrutinized with a high-resolution colonoscope, the prevalence of diminutive adenomas was so high (in the range of 30% to 50%) that some degree of miss rate was unavoidable.

Neoplastic lesions found after a negative colonoscopy. Despite the absence of neoplastic lesions at the initial colonoscopy, benign or malignant metachronous neoplastic lesions can develop in the interval before a second procedure. Interval neoplasia results either from an

TABLE 22. Risk of finding neoplastic lesions in the years after a negative colonoscopy: a retrospective case-control study conducted in patients affiliated with the Medicaid Program for California and having continuous eligibility since at least 60 months preceding the index examination*

	No. cases (Ca)	No. controls (no Ca)	RR†
All Ca; both sexes			
Had no screening	3746	37,155	1.00

Had negative colonoscopy	50	523	0.81

Ca, Cancer; *RR,* relative risk; *Right-sided Ca*, cancer in the proximal colon.
*Colorectal Ca detected up to 5 years after a negative colonoscopy or sigmoidoscopy in a retrospective case-control study conducted in patients affiliated to the Medicaid Program for California and having continuous eligibility since at least 60 months preceding index (G. Triadafilopoulos, unpublished data, 2008).
†Estimation of the RR after a negative procedure.
‡Colonoscopy offers better protection against Ca than sigmoidoscopy but is less effective in prevention in women than in men; the difference is because of poor effectiveness in prevention of right-sided cancer.

initial miss rate or from the development of metachronous evolutive lesions. Interval cancer found shortly after a complete colonoscopy is often a metachronous tumor with rapid growth rather than a lesion missed at the first examination. This particularly applies to flat and depressed nonpolypoid lesions, which are often classified as de novo cancers. The proportion of MIS-positive tumors was analyzed by Sawhney et al[142] in 51 patients, with interval cancers that occurred within 5 years after a colonoscopy and in 112 noninterval colorectal cancers, and a 3.7-fold higher frequency of MIS-positive tumors occurred in the group of interval cancers. Many studies on interval cancers have been conducted in the United States. Squillace et al[143] examined 29 patients after an average interval of 5.7 years of a negative colonoscopy: adenomas were detected in 12 (41.4%). Neugut et al[144] repeated colonoscopy in 99 patients after an average interval of 3 years after the negative first procedure and detected adenomas in 24 patients (24%). Rex et al[145] examined 154 patients after an average interval of 5.5 years after the negative colonoscopy and found adenomas in 41 patients (27%). The Lilly multicenter study (D. Ransohoff, unpublished data, 2008), with 1256 subjects evaluated after an average interval of 5.3 years after a negative colonoscopy, detected adenomas in 201 (16%) and advanced neoplasia in 16 subjects (1.2%).

Evaluation of neoplasia protection after a negative colonoscopy. Despite its limitations, a negative colonoscopy offers an appreciable protection against the risk of developing colorectal cancer.[146] The degree of protection was assessed in a large retrospective case-control study conducted in the United States by using the California MediCal database (Table 22). The occurrence of a negative colonoscopy or sigmoidoscopy in the recent years was explored in patients with (cases) or without cancer (controls). It was concluded that colonoscopy offers better protection than sigmoidoscopy and that such protection was more effective in men than in women, the latter difference being a consequence of a less efficient assessment of the proximal portion of the colon in women. In Japan, the protection afforded against incident neoplastic lesions by a negative colonoscopy was assessed in a retrospective cohort study conducted by 6 distinct centers: the relative risk of finding a incident lesion was very low at 1 year (0.1) and higher at 3 years (0.8) (Table 23).

Neoplasia protection after a colonoscopy with polypectomy. Neoplastic lesions of the colorectal mucosa detected a few years after a colonoscopy with complete resection of all superficial neoplastic lesions may result from 3 possible scenarios: (1) the lesions were missed at the first procedure, (2) new lesions developed during the interval, and (3) lesions were incompletely treated during the first procedure. The proportion of neoplastic lesions detected during the second procedure was explored in Western countries[147-153] and, as shown in Table 24, this figure varies between 32% and 60%. In the United States, the National Polyp Study showed that the percentage of patients with incident adenomas 3 years after the inclusion colonoscopy was 32.0%.[152] In Denmark, in the Funen adenoma follow-up study, the figure was 35% after 4 years, and 60.1% after 8 years.[153] A lower proportion occurs when counting is restricted to metachronous lesions with advanced neoplasia.

The detection of lesions upon surveillance colonoscopy confirms a persistent increased risk in patients with positive findings at the first procedure; however, the risk of recurrence is modulated in relation to the initial findings. In the United States, in the Veterans Affairs cooperative study (Table 25), which was conducted in 13 distinct centers, the relative risk for interval lesions

TABLE 23. Relative risk of recurrent neoplasia in relation to findings at first colonoscopy: retrospective cohort study from the Japan Polyp Study Working Group

Colonoscopy at inclusion	No. cases	No. index lesions detected after follow-up of mean 5.1 y†	Relative risk for finding a index lesion‡ At 1 y	At 3 y
Negative	2006	52	0.1	0.8
Adenoma, up to 5 mm	1655	111	1.0	2.9
Adenoma, more than 5 mm	1123	150	2.5	5.4
Intramucosal cancer	525	66	2.9	5.7

*From the Retrospective Cohort Study from the Japan Polyp Study Working group (T. Matsuda, unpublished data, 2008).
†Index (recurrent) lesions detected during follow-up (mean 5.1 y) after colonoscopy were defined as adenoma >10 mm, intramucosal cancer, invasive cancer (submucosa or deeper); after 5 years, the number of index lesions was higher after polypectomy than after a negative colonoscopy and increased with the severity of initial findings.
‡In relation to the relative risk of finding an index lesion, colonoscopy should be performed after 3 years for patients without polyps or with polyps <5 mm and after 1 year for patients with large polyps or intramucosal cancer.

detected after a negative colonoscopy varied in relation to the increased severity of the index lesions, from 1.92 to 13.56. A similar study has been conducted in 6 centers by the Japan Polyp Working Group (Table 23). The relative risk of recurrent lesions, compared with patients who had a negative colonoscopy at inclusion, varied at 3 years, from 0.8 to 5.7, according to the severity of the index lesions.

STRATEGY OF ENDOSCOPIC DIAGNOSIS

Superficial neoplastic lesions of the colorectal mucosa were first described by using rigid rectosigmoidoscopes, then with fiber-colonoscopes. Since then, there has been a considerable technical evolution, and the most recent electronic video colonoscopes offer high resolution, magnification, and image processing, including the NBI technique. Because of this, the proportion of patients with abnormal findings at colonoscopy is higher than in previous reports; yet seeing more does not mean more clinically relevant abnormalities. High-resolution endoscopy is not a substitute to the careful exploration of the mucosa during endoscopy and expert discriminative analysis.

The 4-steps strategy

Good practice in endoscopic diagnosis requires a step-by-step methodology as the only protection against overdetection and overtreatment.[154]

1. A complete intestinal preparation is an essential first step, because any solid and liquid matter that persists at the surface of the mucosa can mask small nonpolypoid lesions.
2. Detection of an abnormal area is the second step that is performed in a standard visualization, without image processing or chromoscopy. Here, nonpolypoid lesions may easily be missed if the operator lacks the cognitive training to detect a slight change in the color of the mucosa and the deviation of the subepithelial capillaries at the demarcation.
3. Characterization of the lesion is the third step. The routine practice of chromoscopy with indigo carmine (0.1%-0.5% solution) is required to assess the lesion margins and identify elevations or depressions of the lesion's surface. The morphology of the lesion is then identified according to the categories of the Paris classification. Chromoscopy with cresyl violet (0.2% solution) or crystal violet (0.05% solution), achieves a more durable staining, but the use of these stains is reserved for very small areas observed in magnification. The microarchitecture of the epithelial surface is then explored in magnification combined either with chromoscopy or with NBI, and the categories of the pit pattern bring forth a predictive value for histology. The microvascular network is also explored in ''transparency,'' without chromoscopy and with some magnification. NBI is now the criterion standard technique for the classification of the capillary pattern in nonneoplastic and neoplastic lesions.
4. The fourth step is classification and treatment decision and takes into account the lesion's morphology and

TABLE 24. Interval cancer in the years after polypectomy: proportion of recurrent neoplastic lesions found in the endoscopic surveillance after a colonoscopy with complete resection of the index lesions*

Investigator/country	Study	No. patients	Interval (years of follow-up)	% Patients with neoplasia	% Patients with advanced neoplasia†
Winawer et al,[152] U.S.	Surveillance National Polyp Study	766	3	32	3.3
Jørgensen et al,[153] Denmark	Surveillance Funen trial	1056 at inclusion	4	35.5	8.6
Alberts et al,[147] U.S.	Controls of fiber trial	584	3	51.2	31.4
Schatzkin et al,[151] U.S.	Controls of celecoxib trial	947	4	39.5	7
Arber et al,[148] Israel	Controls of fiber trial	557	3	49.3	10.4
Baron et al,[150] U.S.	Controls of rofecoxib trial	1218	3	55	17.4
Bertagnolli et al,[149] U.S.	Controls of celecoxib trial	613	3	60.7	17.2

*Recurrent lesions result either from incomplete polypectomy, from missed detection during the first procedure, or from fast-developing incident lesions.
†Advanced neoplasia, defined as tubular adenoma, at least 10-mm villous adenoma, high-grade atypia, or Ca.

TABLE 25. Relative risk of recurrent neoplasia in relation to findings at first colonoscopy: estimation of the relative risk of finding an advanced neoplasia during a 5-year surveillance after screening colonoscopy in relation to the baseline findings*

Baseline finding at colonoscopy	Advanced neoplasia, no. (%)†	Relative risk
No neoplasia (n = 298)	7 (2.4)	1.00
Neoplasia (n = 895)		
Tubular adenoma: 1 or 2, less 10 mm	23 (4.6)	1.92
Tubular adenoma: 3 and more, less 10 mm	15 (11.9)	5.01
Tubular adenoma: over 10 mm	19 (15.5)	6.40
Villous adenoma	13 (16.1)	6.05
Adenoma with high-grade atypia	8 (17.4)	6.87
Cancer	8 (34.8)	13.56

*Results of the Veterans Affairs Cooperative Study no. 380 (D. Lieberman, unpublished data, 2008) in 2007. There is a strong association between the occurrence of advanced neoplasia and the results of the baseline screening colonoscopy.
†Advanced neoplasia is defined as tubular adenoma at least 10-mm, villous adenoma, adenoma with high-grade atypia or cancer.

location. The treatment decision offers the choice between abstention, endoscopic resection, or surgery. The en bloc endoscopic resection of nonpolypoid lesions may require the complex technique of endoscopic submucosal dissection.

A pragmatic choice for treatment

1. Superficial lesions in the proximal portion of the colon are often more advanced or evolutive than those in the distal portion of the colon; most small HP lesions are nonneoplastic; large HP lesions in the proximal portion of the colon often host high-grade neoplasia.
2. Large polypoid or nonpolypoid lesions are more at risk of malignancy; most small lesions that show a 0-IIa or 0-IIb morphology host low-grade neoplasia; lesions that show a 0-IIc depressed morphology often host high-grade neoplasia with frequent submucosal invasion.

Quality control in colonoscopy

Major requirements in quality control include the use of a new-generation high-resolution video colonoscope, the routine application of chromoscopy with indigo carmine as a first step in the characterization of each lesion that, in turn, should be attributed to a subtype according to the Paris classification. This subtyping must be mentioned in the endoscopy report (as well as in the pathology report if the lesion is resected). When there is a suspicion of high-grade neoplasia, magnifying endoscopy, combined with image processing, has the capacity to evaluate, with more precision, the severity of neoplasia and its possible invasion of the submucosa.

ACKNOWLEDGMENT

The initiative to conduct the workshop was stimulated by the discussions about the program developed by the European Commission for the Development of Quality Assurance for Colorectal Cancer Screening.

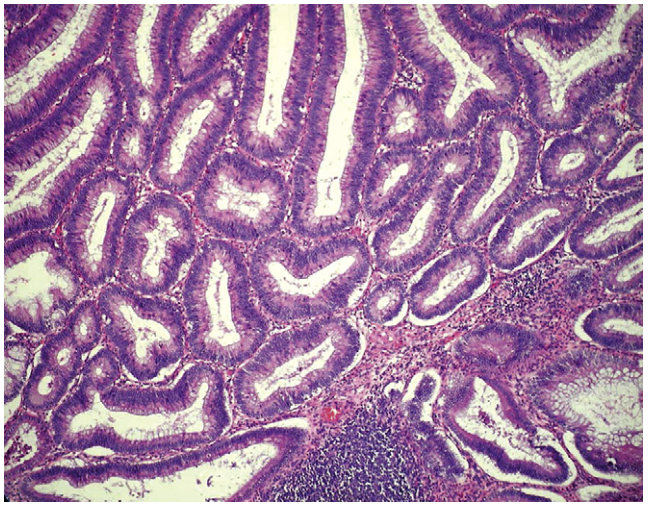
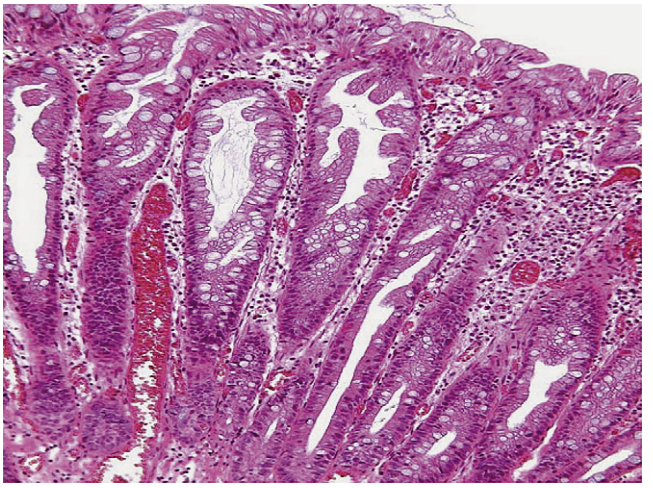
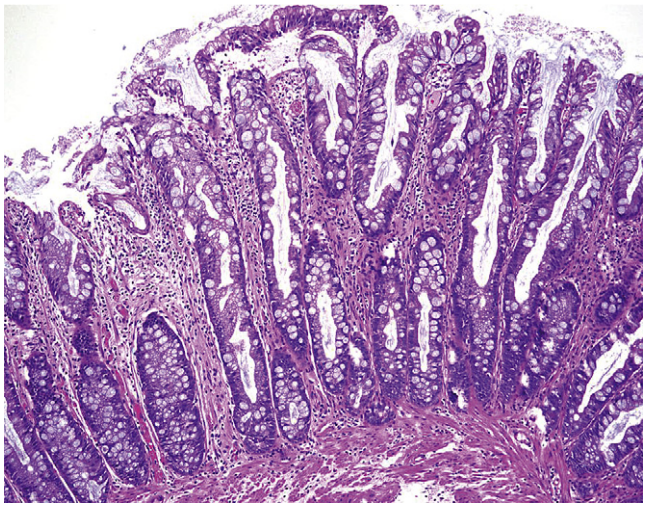
IMAGE ATLAS



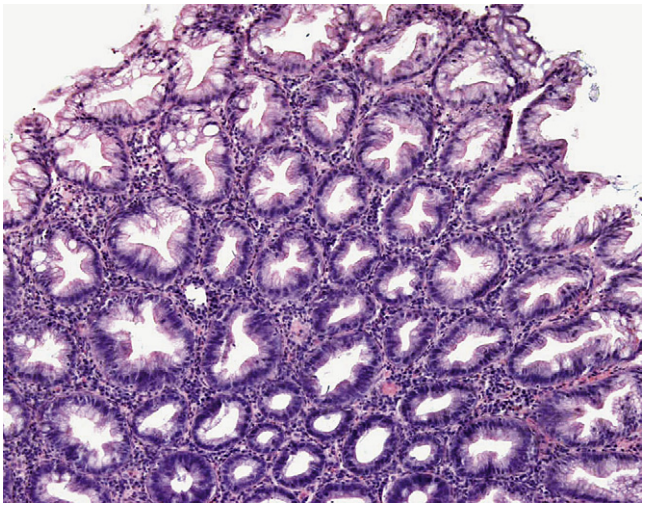
A1. Histopathology of tubular adenoma. Hyperchromatic palisading elongated nuclei in highly prismatic columnar epithelium (H&E, orig. mag. × 100).



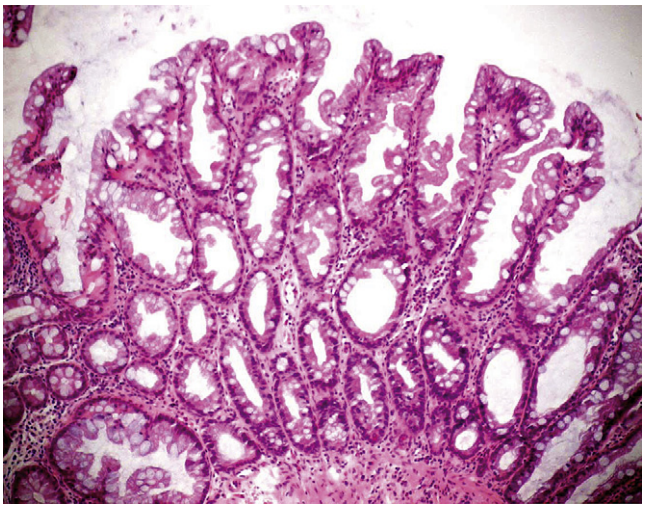
A3. Histopathology of HP lesion. Serration in upper half of crypts (H&E, orig. mag. × 150).



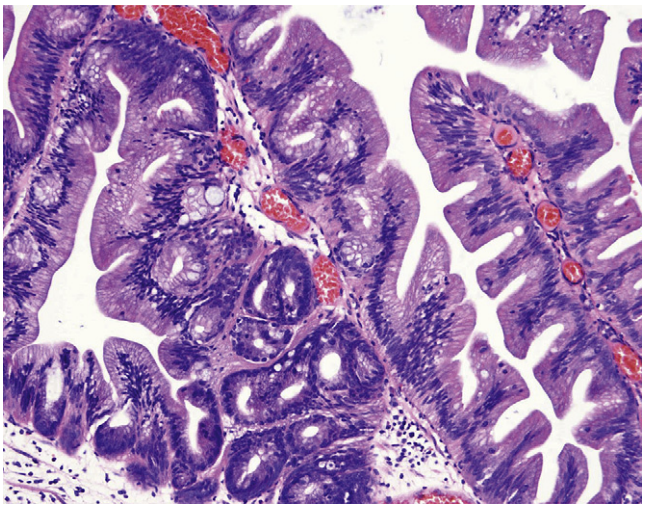
A2. Histopathology of HP lesion. Serration in upper half of crypts. Normal proliferation in basal half: small, regular, basal orientated nuclei (H&E, orig. mag. × 100).



A4. Histopathology of HP lesion. Transverse section of the serrated crypts (H&E, orig. mag. × 100).

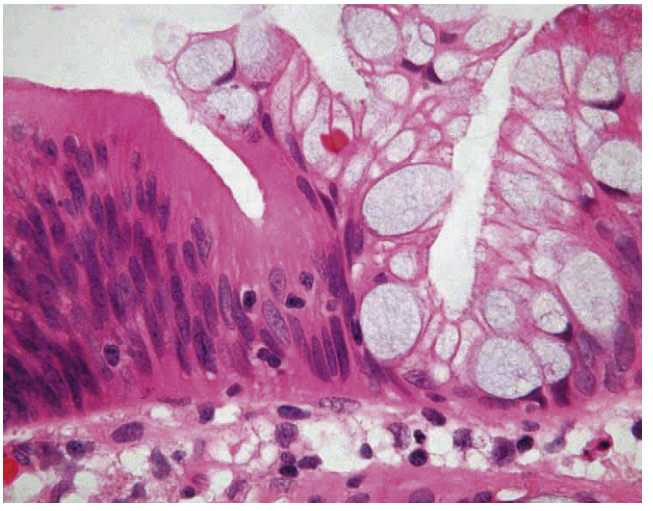


A5. Histopathology of sessile serrated lesion. Dilated crypts in basal area. No cell atypia (H&E, orig. mag. × 100).

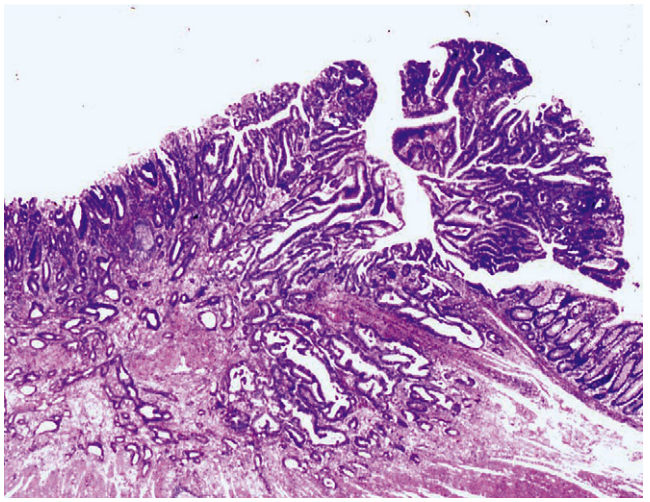


A7. Histopathology of serrated adenoma. Intraepithelial microacini in upper half. Low-grade intraepithelial neoplasia, eosinophilic cytoplasm, elongated nuclei (H&E, orig. mag. × 150).

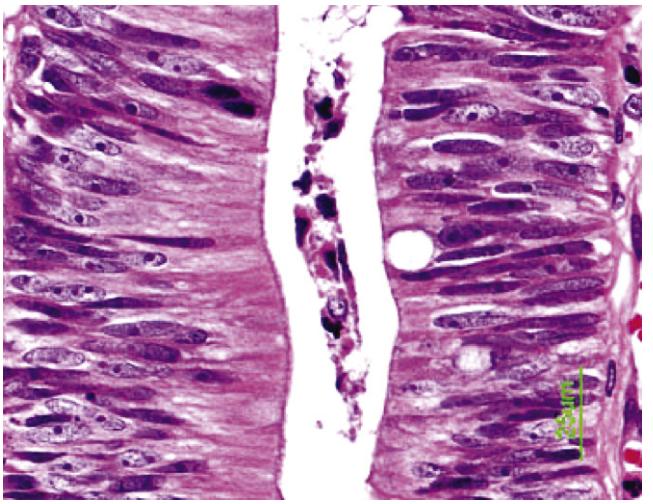
A6. Histopathology of sessile serrated lesion. Proliferation, architectural distortion: serration in basal half of crypts, enlarged with horizontal growth; abundant mucus (H&E, orig. mag. × 120).



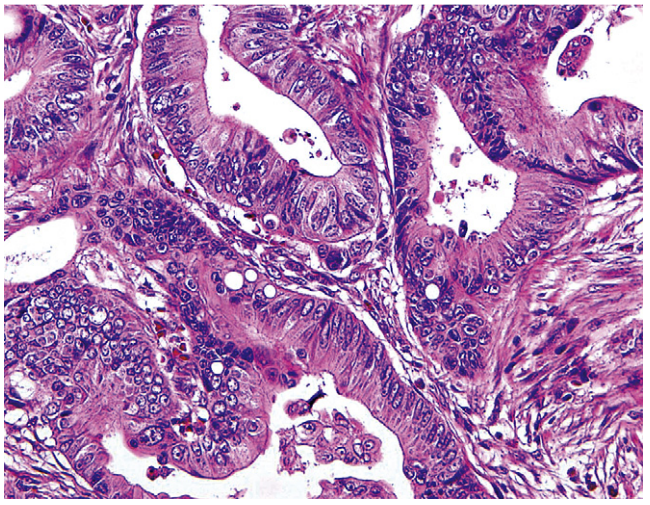
A8. Histopathology of mixed polyp: adenoma (*left*), with elongated hyperchromatic nuclei; sessile hyperplastic polyp with goblet cells (*right*) (H&E, orig. mag. × 300).



A9. Histopathology of neoplastic lesion, 8 mm, 0-IIa, panoramic view (H&E, orig. mag. × 50).

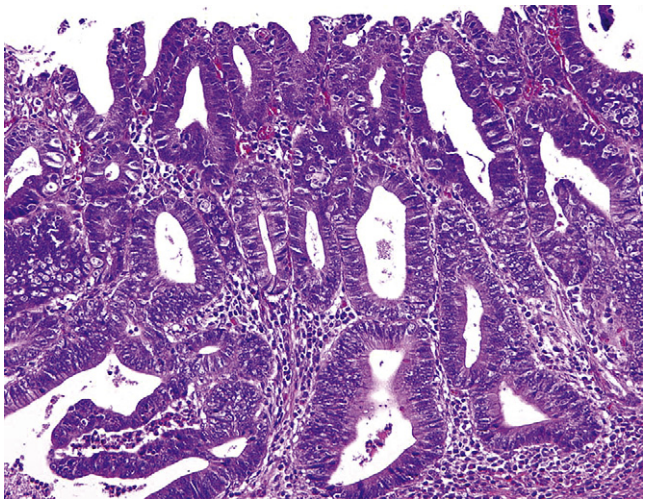


A11. Histopathology of neoplastic lesion, low-grade cell atypia, well-differentiated intramucosal adenocarcinoma; hyperchromatic elongated nuclei in basal arrangement (H&E, orig. mag. × 300).

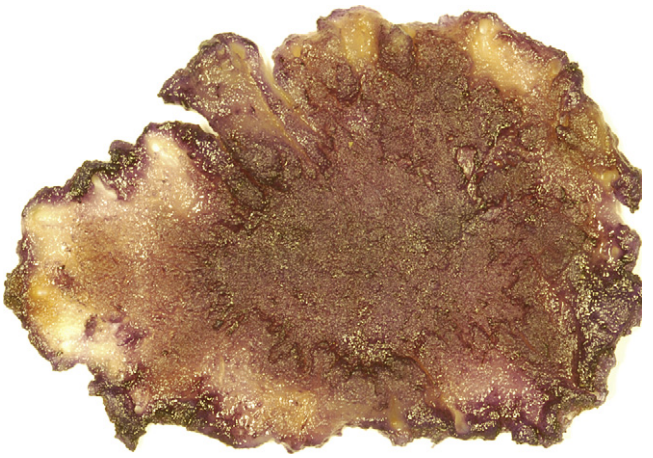


A10. Same case as in image no. 9. Low-grade cell atypia, well-differentiated adenocarcinoma, no residual adenoma; submucosal invasion (H&E, orig. mag. × 150).

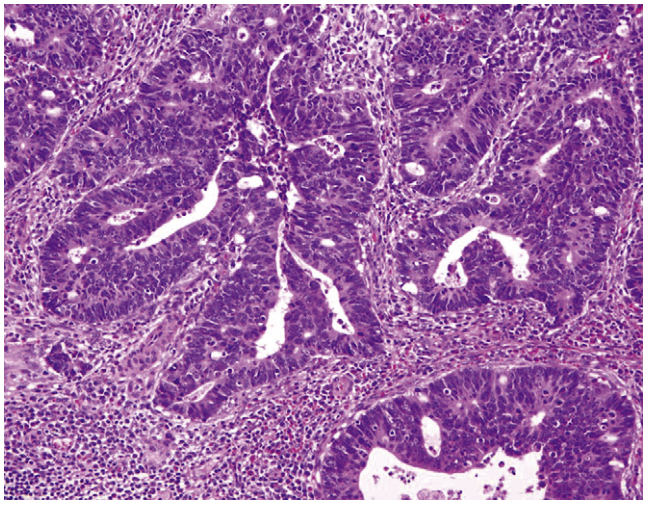
A12. Histopathology of neoplastic lesion, 7 mm, 0-IIa, panoramic view (H&E, orig. mag. × 40).



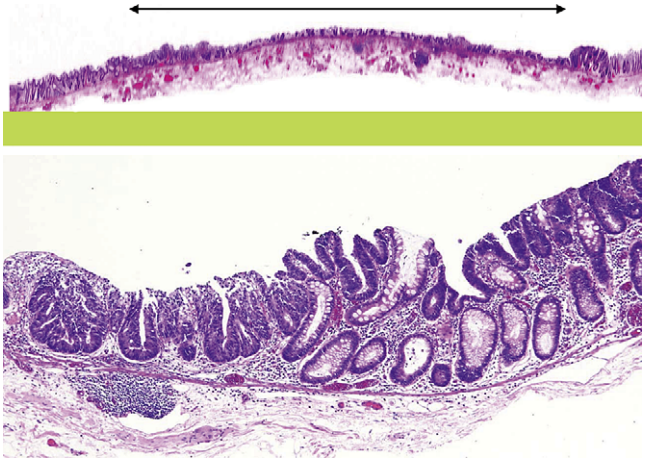
A13. Same case as in image no. 12. High-grade cell atypia, well-differentiated intramucosal adenocarcinoma, no residual adenoma; nuclei up to apical pole of cells (H&E, orig. mag. × 100).



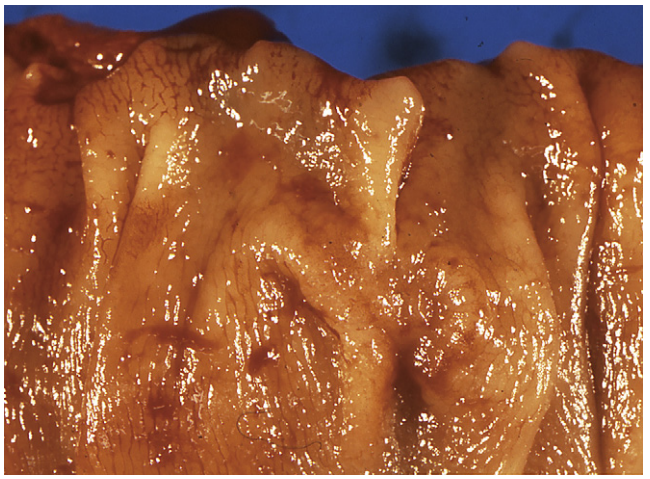
A15. Operative specimen after fixation, mucosectomy; neoplastic lesion 20 mm, 0-IIc.



A14. Histopathology of neoplastic lesion, 5 mm, 0-IIa + 0-IIc; high-grade cell atypia, well-differentiated adenocarcinoma, submucosal invasion; no residual adenoma; nuclei up to apical pole of cells (H&E, orig. mag. × 150).

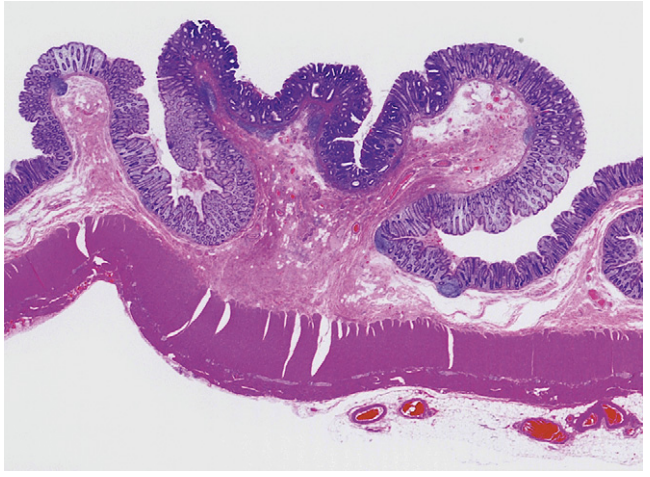


A16. Same case as in image no. 15. Panoramic view, showing a large flat depression (*upper*) (H&E, orig. mag. × 20); well-differentiated intramucosal adenocarcinoma, no residual adenoma (*lower*) (H&E, orig. mag. × 50).

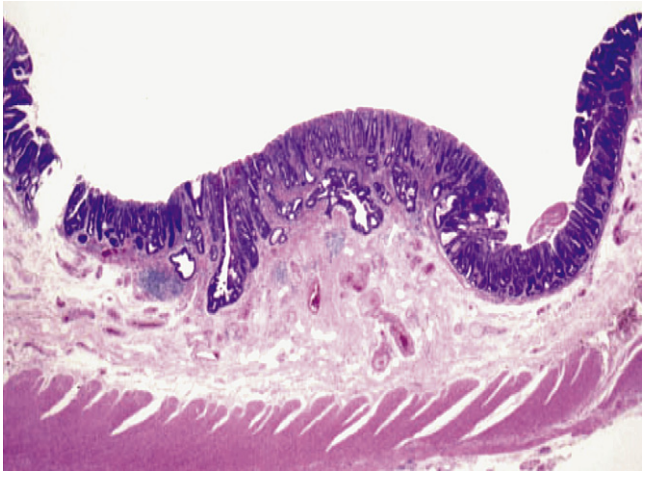


A17. Operative specimen, fresh, neoplastic lesion 7 mm, 0-IIc.

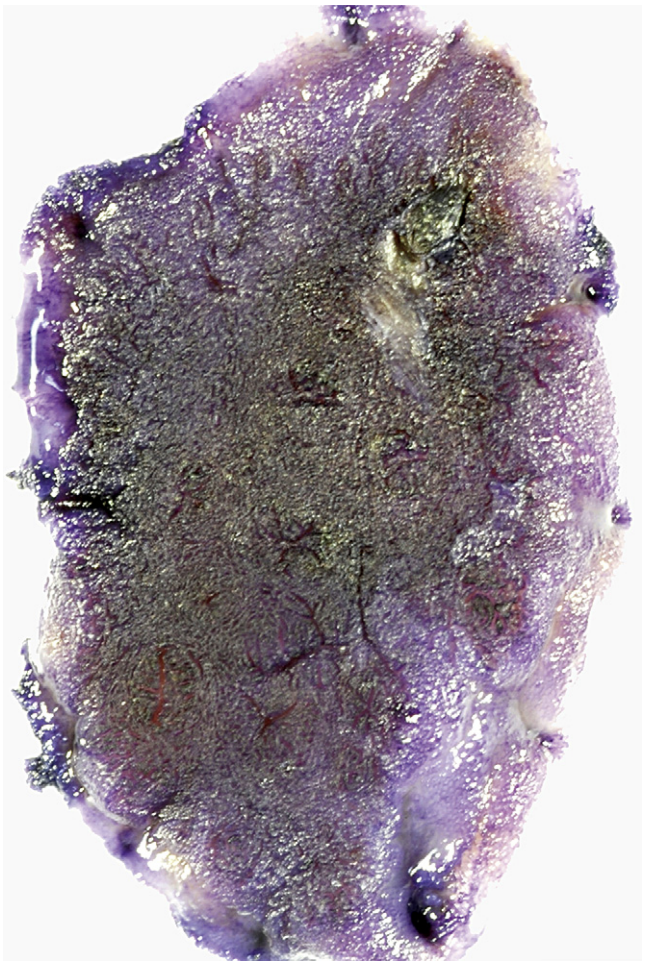
A19. Operative specimen after fixation. Neoplastic lesion, 20 mm, 0-IIc, deep mucosal depression, fold convergence suggestive of invasive cancer.



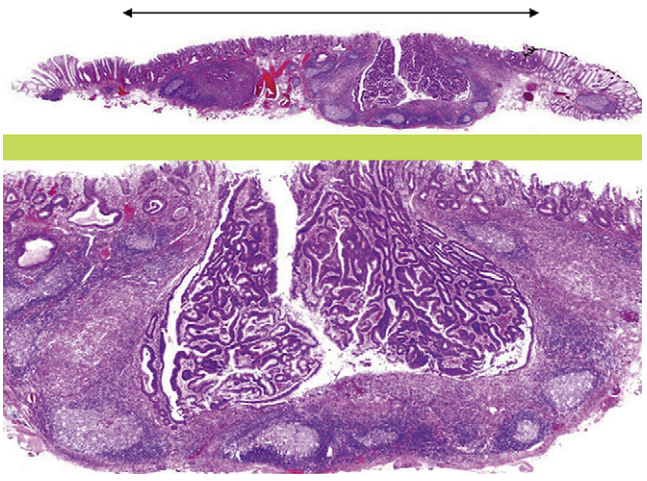
A18. Same case as in image no. 17. Well-differentiated intramucosal adenocarcinoma, no residual adenoma (H&E, orig. mag. × 40).



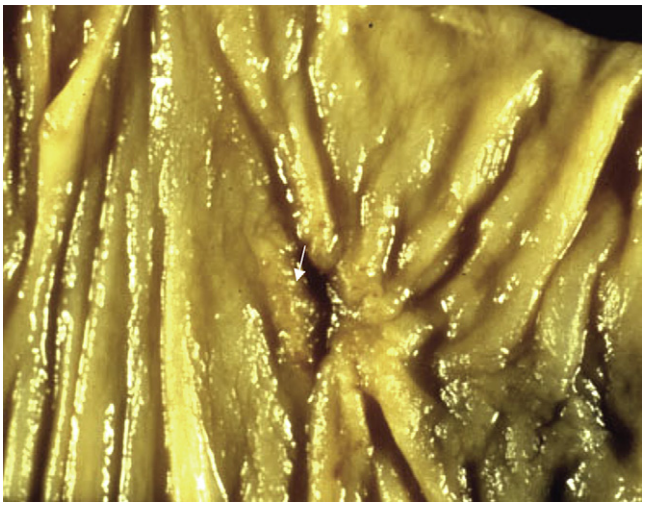
A20. Same case as in image no. 19. Well-differentiated adenocarcinoma, submucosal invasion, no residual adenoma (H&E, orig. mag. × 60).



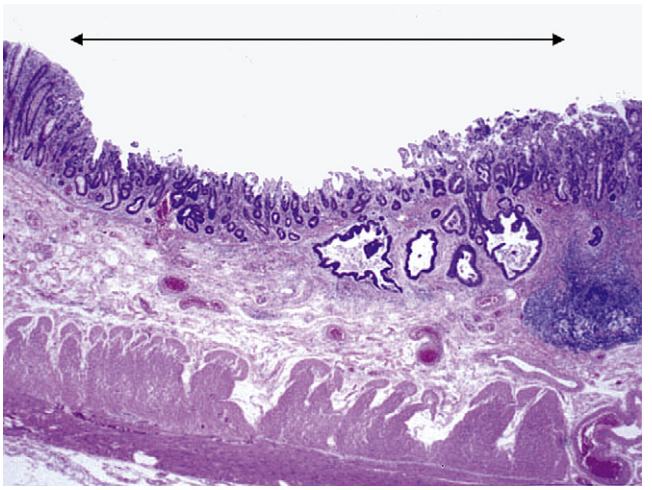
A21. Operative specimen after fixation, mucosectomy, neoplastic lesion, 20 × 13 mm, 0-IIc.



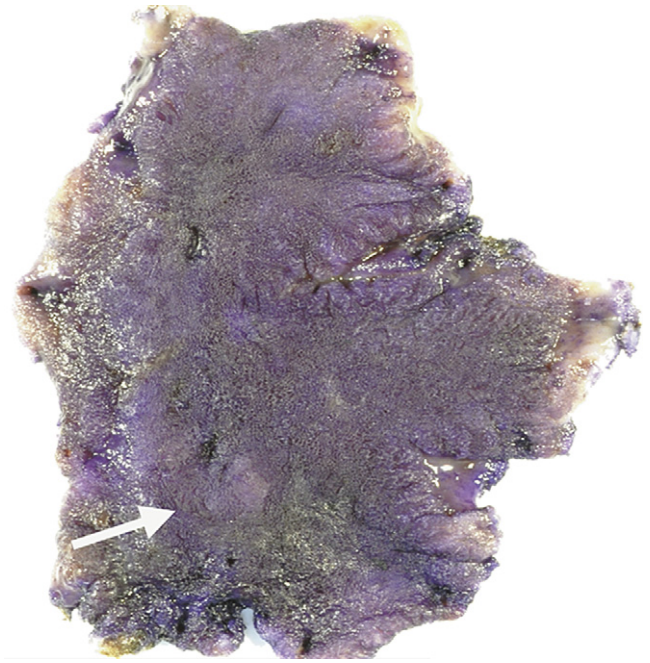
A22. Same case as in image no. 21. Panoramic view, central elevation in a shallow depression (*upper*) (H&E, orig. mag. × 20); well-differentiated adenocarcinoma, submucosal invasion, 1500 μm in depth, no residual adenoma (*lower*) (H&E, orig. mag. × 50).



A23. Operative specimen after fixation, neoplastic lesion, 8 mm, 0-IIc, deep depression; convergence of fold suggestive of invasive cancer.

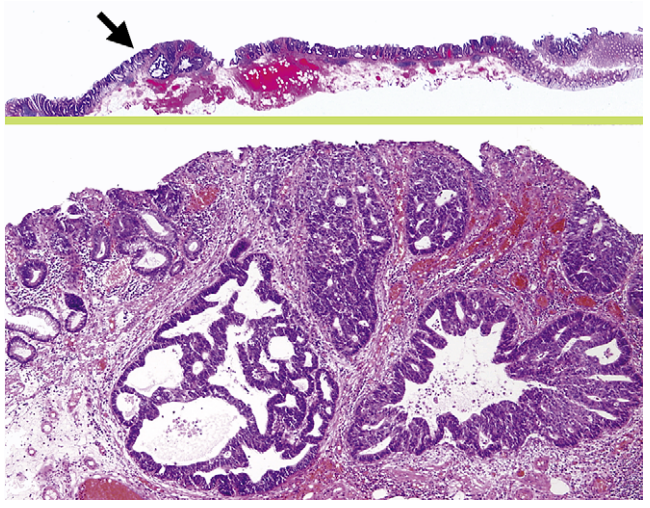


A24. Same case as in image no. 23. Well-differentiated adenocarcinoma, submucosal invasion at the level of the depression, no residual adenoma (H&E, orig. mag. × 60).

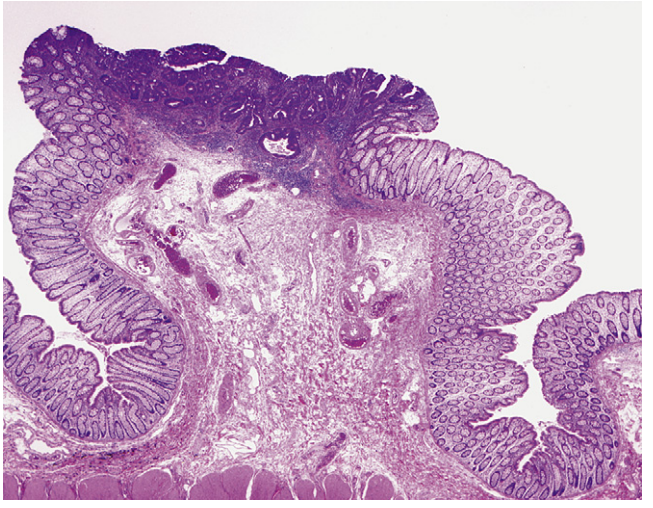


A25. Operative specimen after fixation, mucosectomy, neoplastic lesion, 39 × 33 mm, 0-IIc + IIa, depressed area with a small elevated nodule (*arrow*).

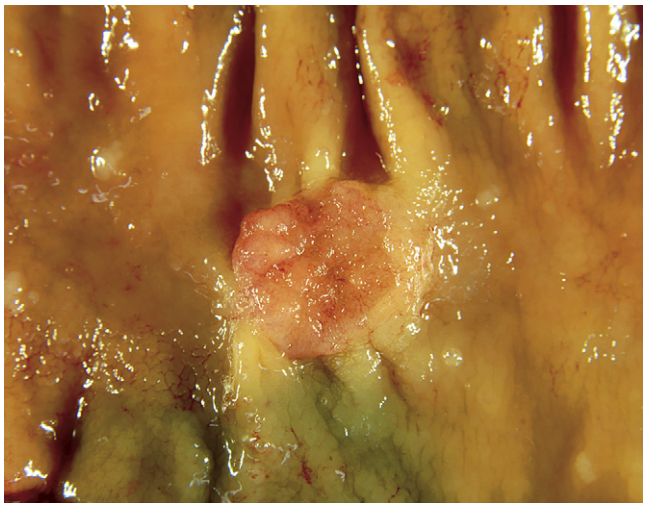
A27. Operative specimen after fixation, neoplastic lesion 5 mm, 0-IIa + IIc.



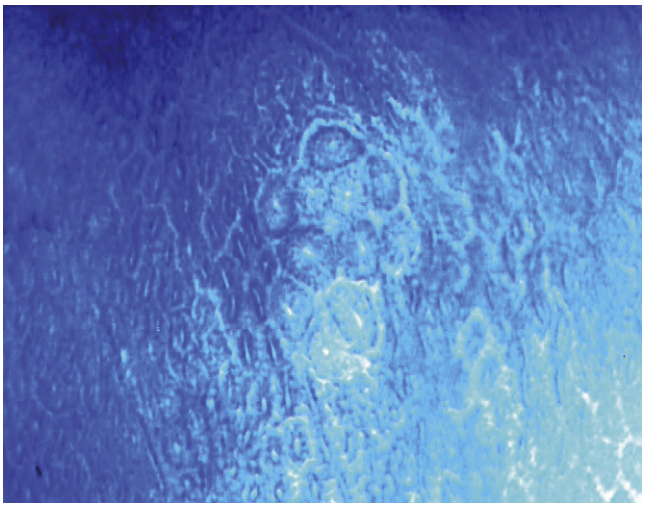
A26. Same case as in image no. 25. Panoramic view of lesion (*upper*) (H&E, orig. mag. × 20); moderately differentiated adenocarcinoma, submucosal invasion, no residual adenoma (*lower*) (H&E, orig. mag. × 50).



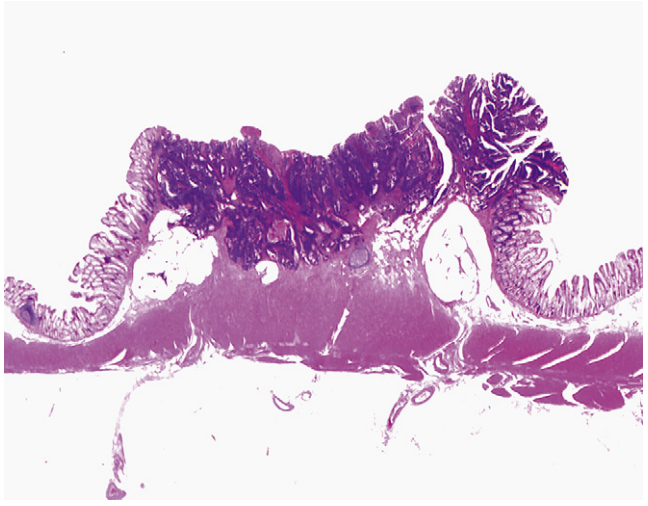
A28. Same case as in image no. 27. Panoramic view of depressed surface of the lesion; well-differentiated adenocarcinoma, submucosal invasion, no residual adenoma (H&E, orig. mag. × 60).



A29. Operative specimen, fresh, neoplastic lesion, 13 mm, 0-IIa + IIc, slightly elevated tumor, with irregular central depression.

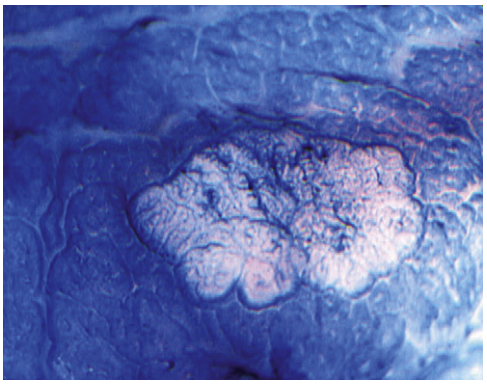


A31. Endoscopy (magnification ×100), chromoscopy with methylene blue 0.01%; ACF nonneoplastic in the rectum; cluster of enlarged crypts.

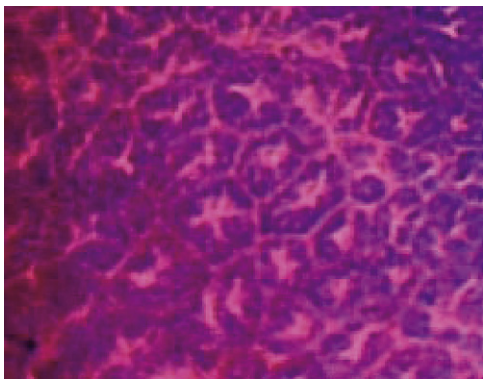


A30. Same case as in image no. 29. Moderately differentiated advanced adenocarcinoma, massive submucosal invasion that involved muscularis propria, no residual adenoma (H&E, orig. mag. × 40).

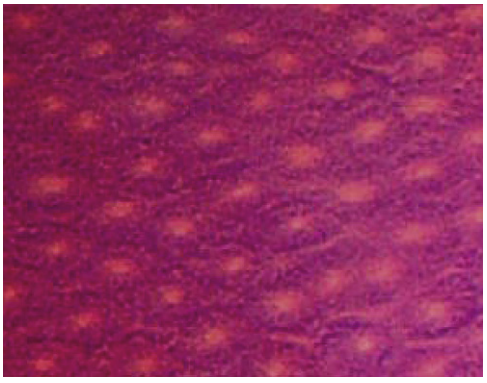
A32. Endoscopy (magnification ×100) and NBI; ACF, nonneoplastic; cluster of enlarged crypts; no pericryptic vascular change.



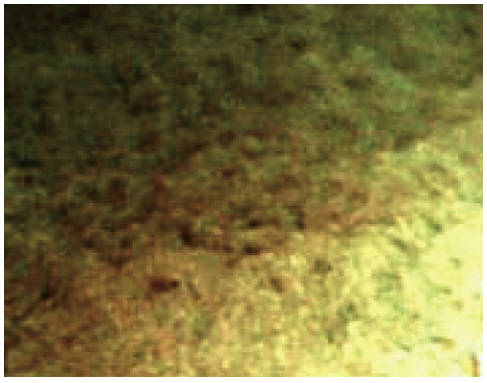
A33. Endoscopy (magnification ×100), chromoscopy with methylene blue 0.01%; ACF, neoplastic; cluster of enlarged, disordered crypts.



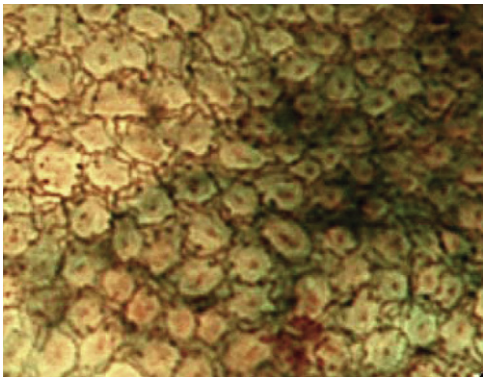
A36. Endoscopy (magnification), chromoscopy with cresyl violet; HP lesion; pit pattern II, star-like crypt openings.



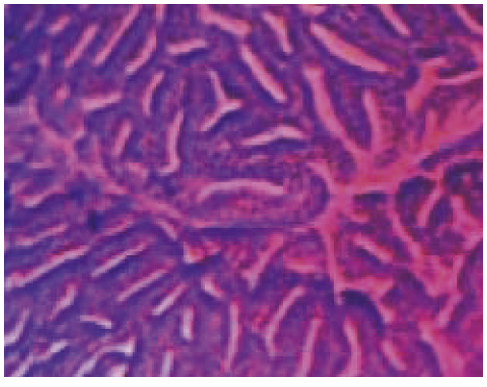
A34. Endoscopy (magnification), chromoscopy with cresyl violet; normal colonic mucosa. Pit pattern I.



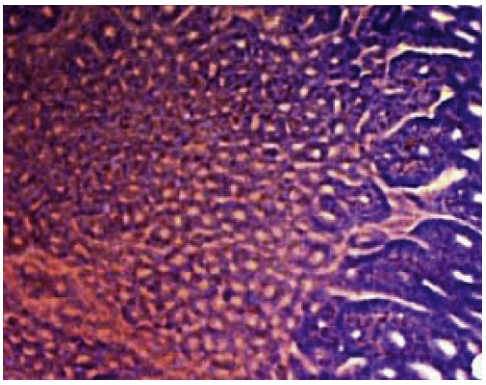
A37. Endoscopy (magnification), NBI; HP lesion; vascular pattern "faint."



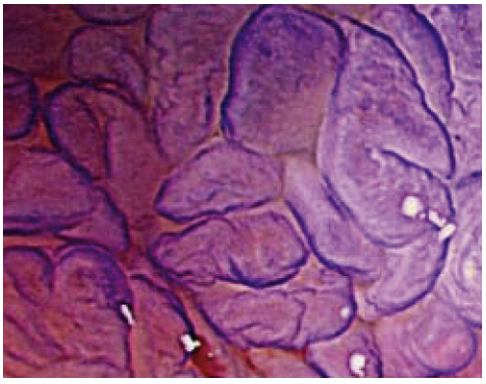
A35. Endoscopy(magnification), NBI; normal colonic mucosa; vascular pattern "normal."



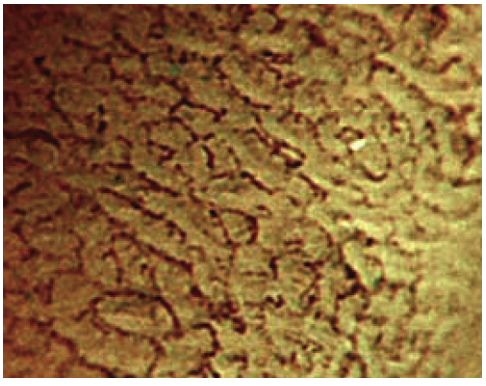
A38. Endoscopy (magnification), chromoscopy with cresyl violet, neoplastic lesion, premalignant; pit pattern IIIL, large crests.



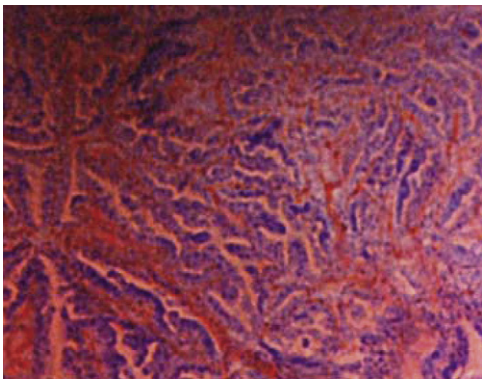
A39. Endoscopy (magnification), chromoscopy with cresyl violet; neoplastic lesion, premalignant; pit pattern IIIS, narrow crypt openings.



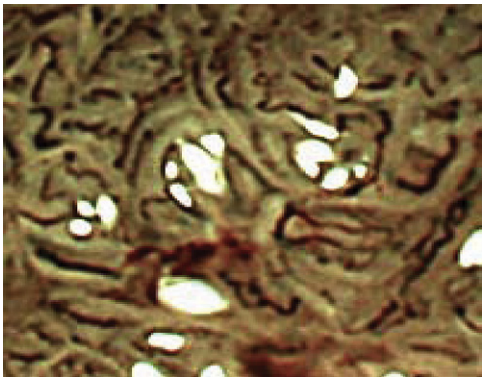
A40. Endoscopy (magnification), chromoscopy with cresyl violet, neoplastic lesion, premalignant; pit pattern IV, branched crests.



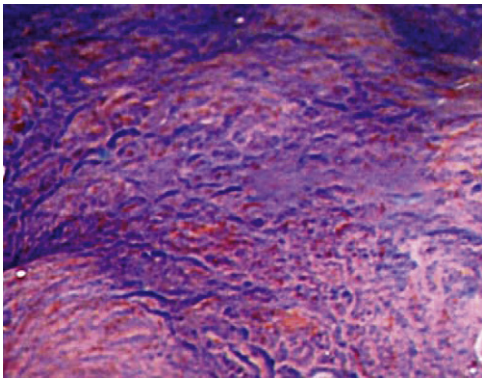
A41. Endoscopy (magnification), NBI; neoplastic lesion, premalignant; vascular pattern ''network.''



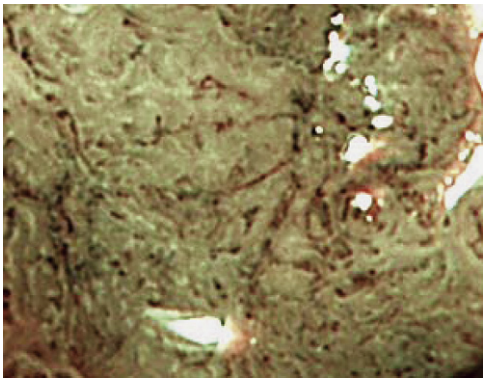
A42. Endoscopy (magnification), chromoscopy with cresyl violet carcinoma; pit pattern Vi, irregular.



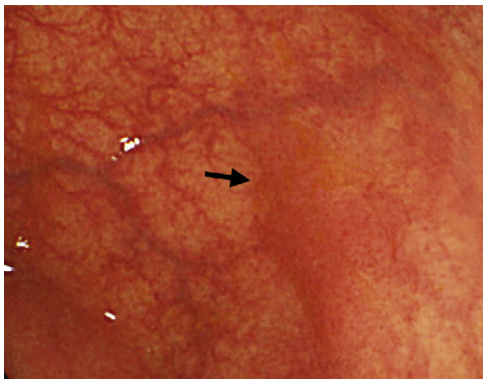
A43. Endoscopy (magnification), NBI; carcinoma; vascular pattern ''irregular.''



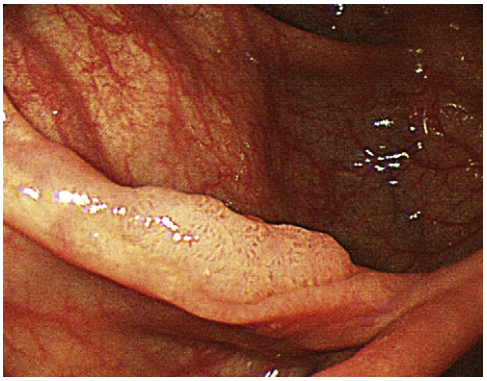
A44. Endoscopy (magnification), chromoscopy with cresyl violet; carcinoma; pit pattern VN, nonstructural.



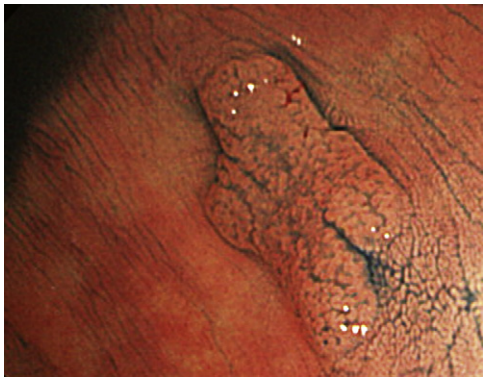
A45. Endoscopy (magnification), NBI; carcinoma; vascular pattern "sparse."



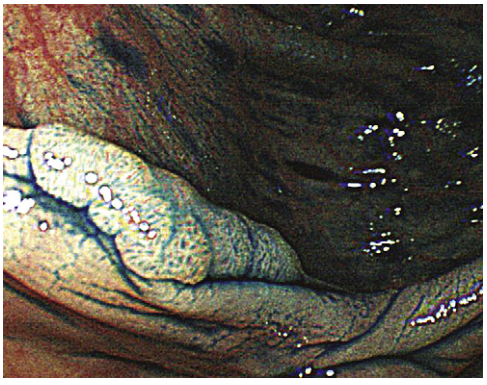
A48. Endoscopy, slightly elevated neoplastic lesion (*arrow*), 0-IIa.



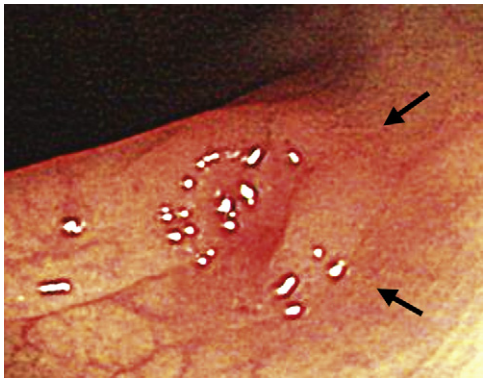
A46. Endoscopy, slightly elevated neoplastic lesion, 0-IIa.



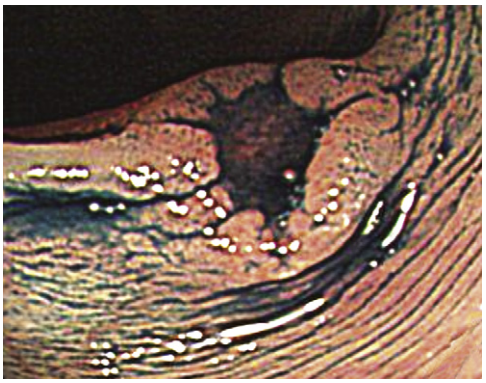
A49. Same case as in image no. 48, chromoscopy with indigo carmine.



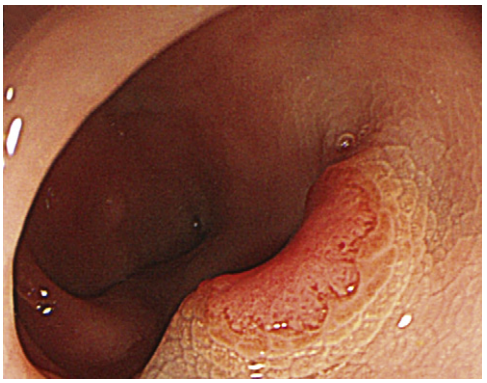
A47. Same case as in image no. 46, chromoscopy with indigo carmine.



A50. Endoscopy, depressed neoplastic lesion (*arrows*), 0-IIc.

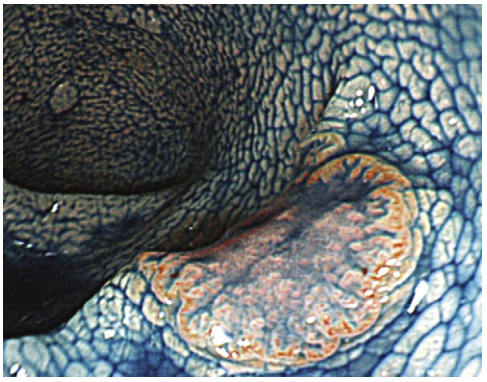


A51. Same case as in image no. 50, chromoscopy with indigo carmine.

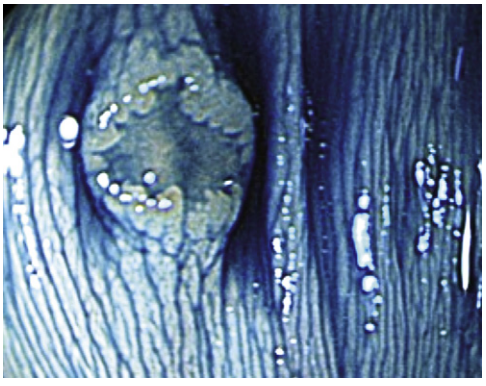


A54. Endoscopy, depressed neoplastic lesion, 7 mm, 0-IIc.

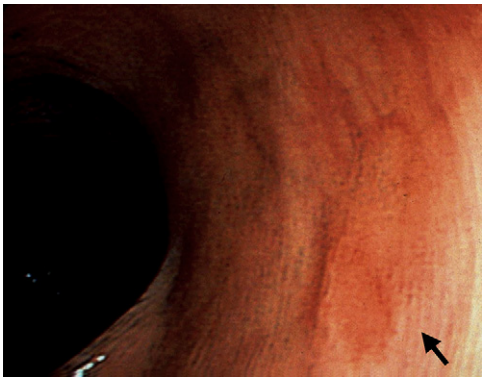
A52. Endoscopy, depressed neoplastic lesion, 4 mm, 0-IIc; the lesion appears as elevated above the surface; can be mistaken for 0-IIa.



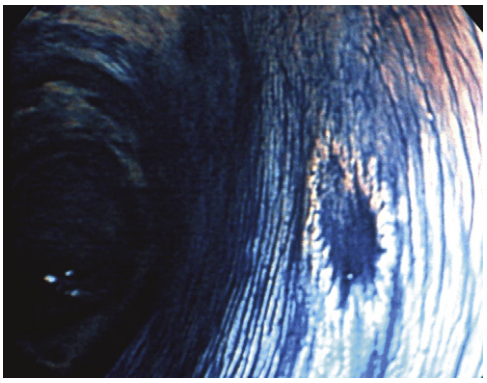
A55. Same case as in image no. 54, chromoscopy with indigo carmine.



A53. Same case as in image no. 52, chromoscopy with indigo carmine.

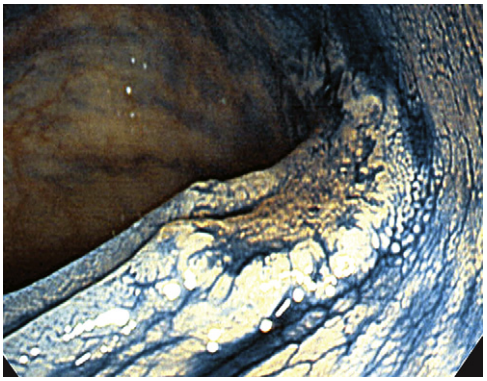


A56. Endoscopy, depressed neoplastic lesion (*arrow*), 4 mm, 0-IIc, intramucosal carcinoma.

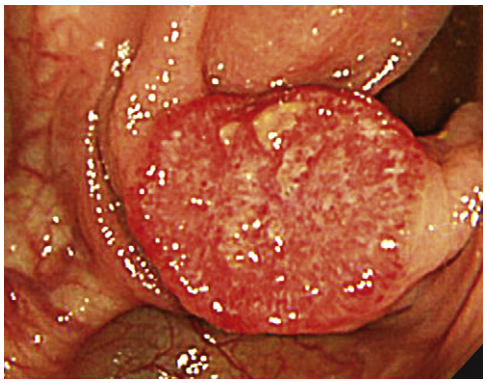


A57. Same case as in image no. 56, chromoscopy with indigo carmine.

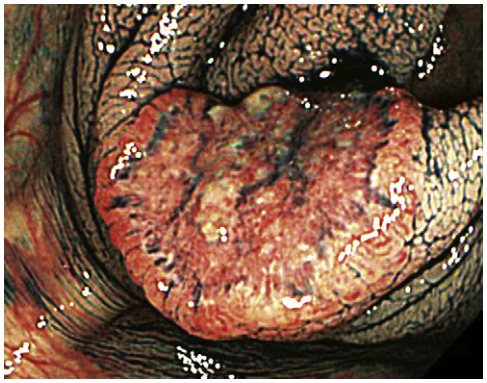
A58. Endoscopy, depressed neoplastic lesion, 7 mm, 0-IIc, carcinoma with submucosal invasion s1.



A59. Same case as in image no. 58, chromoscopy with indigo carmine.

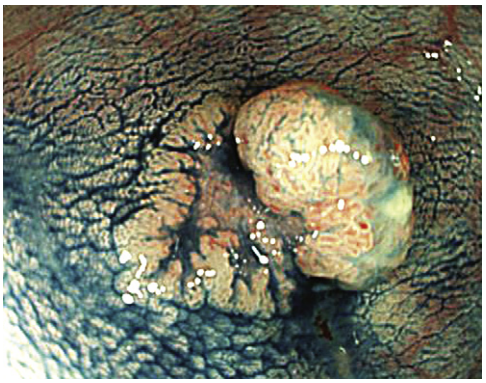


A60. Endoscopy, slightly elevated and depressed neoplastic lesion, 0-IIa + 0-IIc.

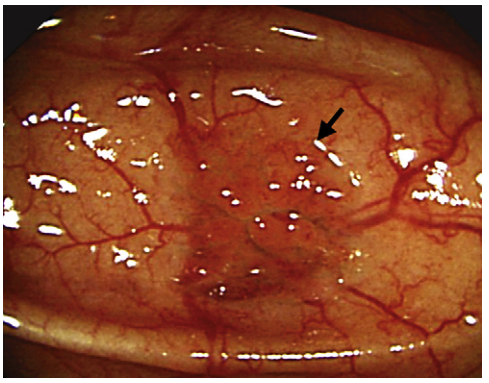


A61. Same case as in image no. 60, chromoscopy with indigo carmine.

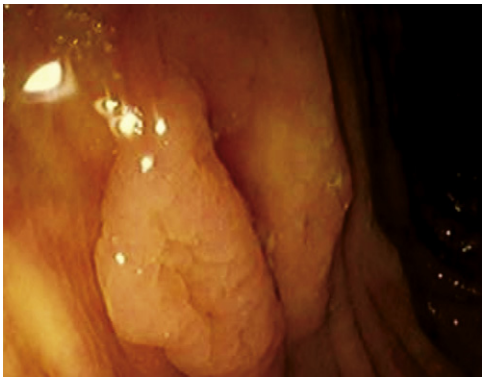
A62. Endoscopy, depressed and polypoid sessile neoplastic lesion, 0-IIc, 0-Is.



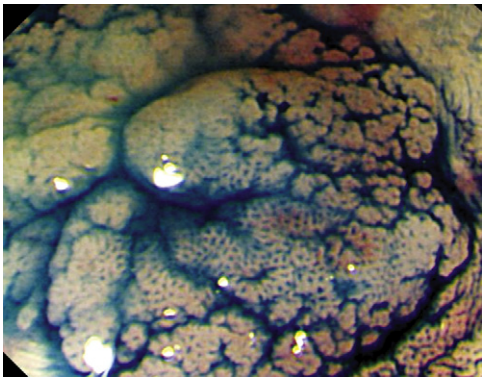
A63. Same case as in image no. 62, chromoscopy with indigo carmine.



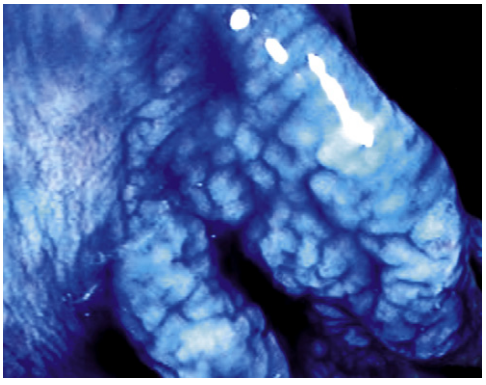
A66. Endoscopy, sessile serrated lesion (*arrow*), 0-IIa.



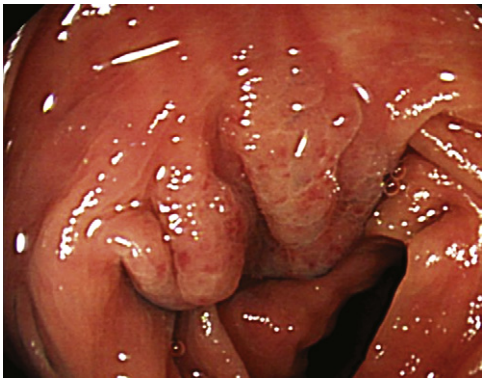
A64. Endoscopy, HP lesion, 0-IIa.



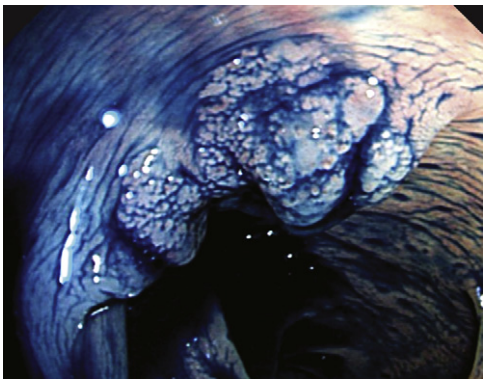
A67. Same case as in image no. 66, chromoscopy with indigo carmine; star-shaped opening of pits in some areas.



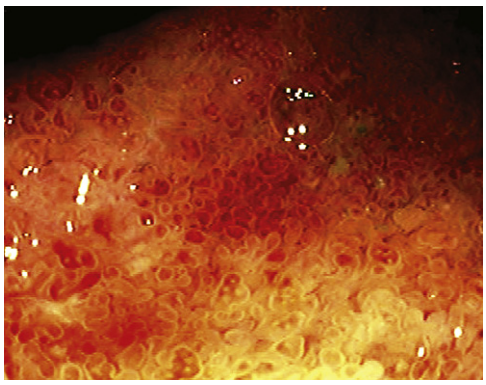
A65. Same case as in image no. 64, chromoscopy with indigo carmine.



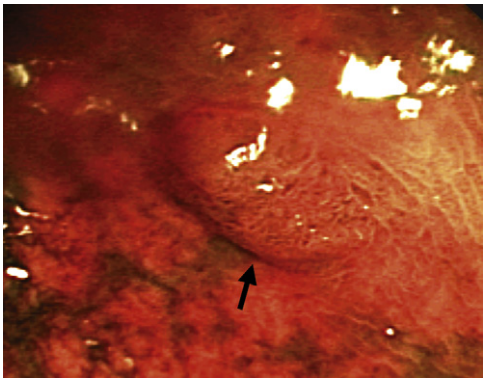
A68. Endoscopy, sessile serrated lesion, 0-IIa.



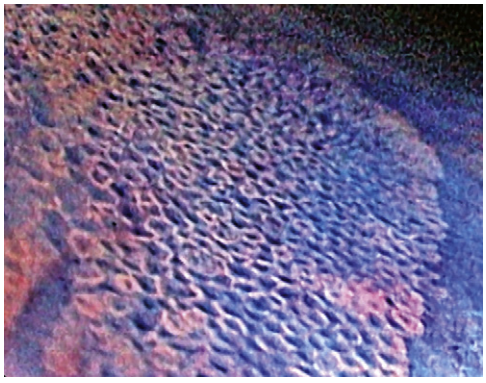
A69. Same case as in image no. 68, chromoscopy with indigo carmine.



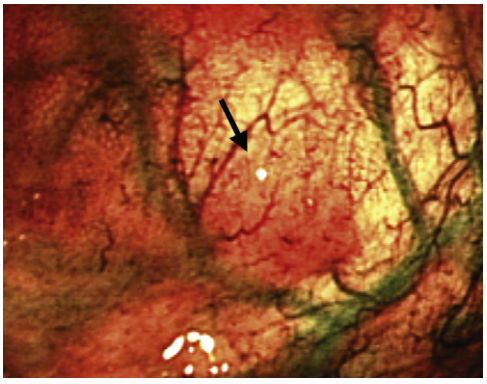
A72. Endoscopy (magnification); ulcerative colitis, quiescent: a flat villous area.



A70. Endoscopy, sessile serrated lesion, with NBI, 0-IIa.

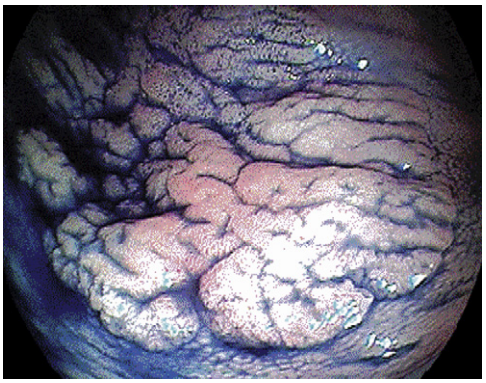


A73. Endoscopy (magnification), chromoscopy with indigo carmine: ulcerative colitis, quiescent; a flat HP lesion with large crypt openings 0-IIb.

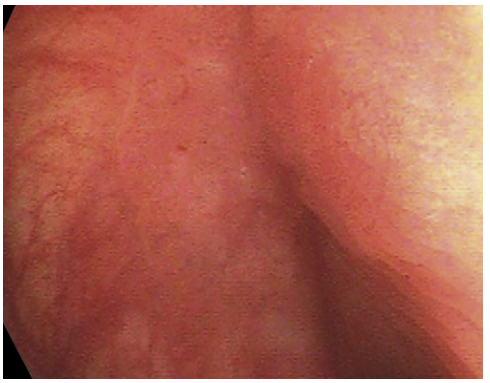


A71. Endoscopy, sessile serrated lesion (*arrow*), with NBI, 0-IIb.

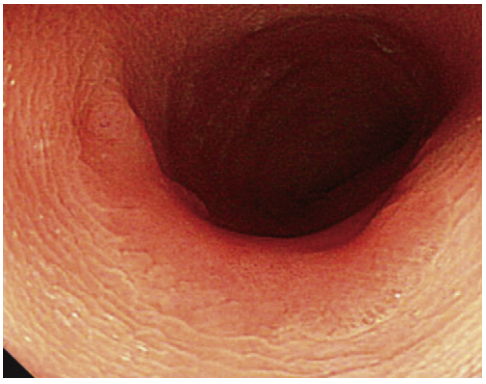
A74. Endoscopy, LST lesion, nongranular, slightly elevated 0-IIa.



A75. Same case as in image no. 74, chromoscopy with indigo carmine.

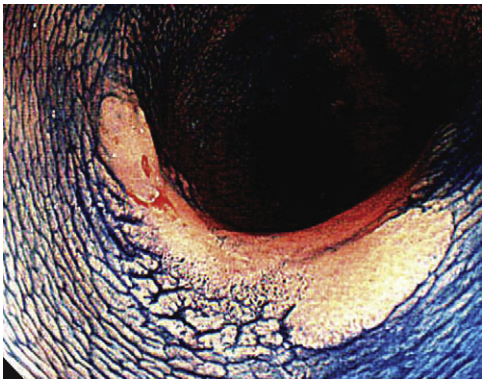


A78. Endoscopy, LST lesion, nongranular, pseudodepressed, 0-IIa + 0-IIc.

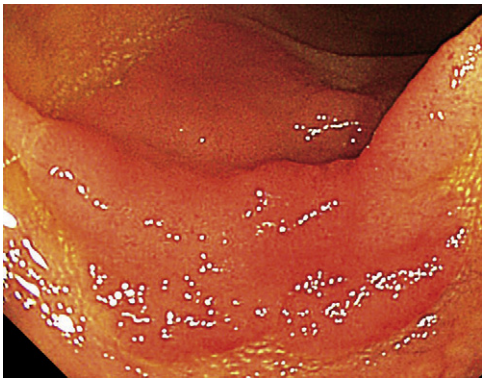


A76. Endoscopy, LST lesion, nongranular, slightly elevated 0-IIa.

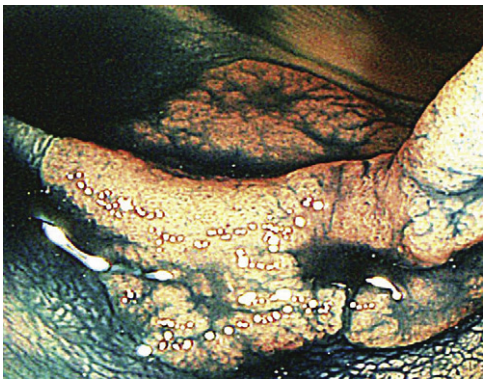
A79. Same case as in image no. 78, chromoscopy with indigo carmine.



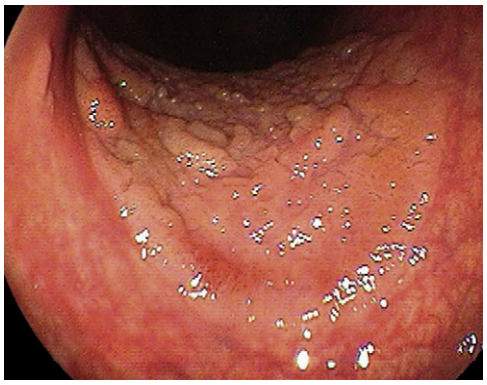
A77. Same case as in image no. 76, chromoscopy with indigo carmine.



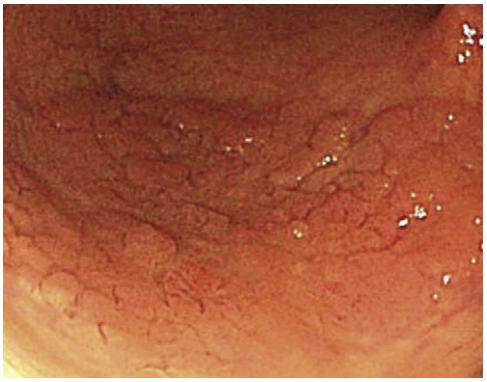
A80. Endoscopy, LST lesion, nongranular, slightly elevated 0-IIa.



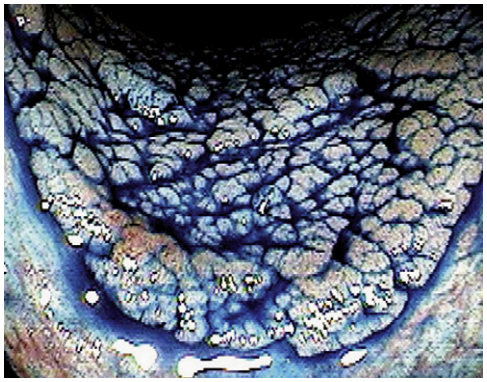
A81. Same case as in image no. 80, chromoscopy with indigo carmine.



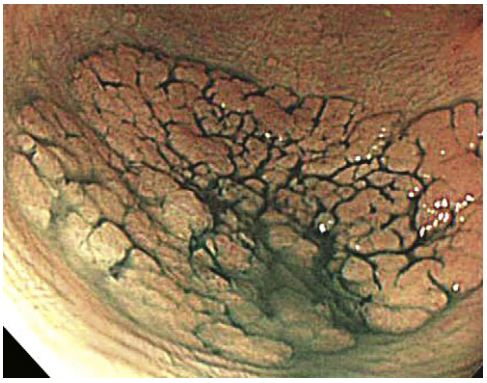
A84. Endoscopy, LST lesion, granular, homogenous, 0-IIa.



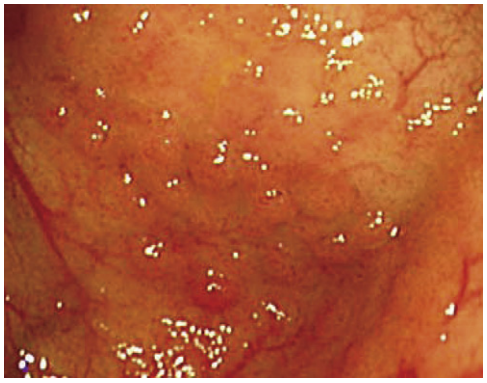
A82. Endoscopy, LST lesion, granular, homogenous, 0-IIa.



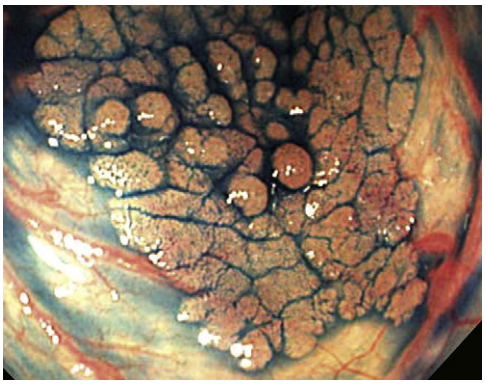
A85. Same case as in image no. 84, chromoscopy with indigo carmine.



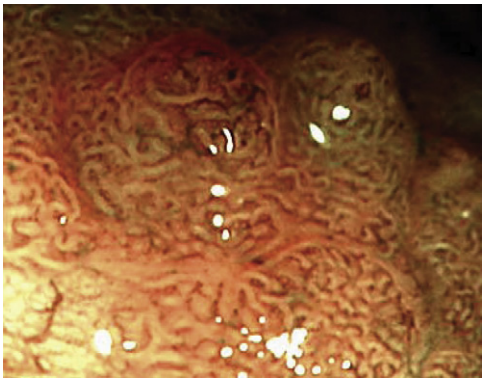
A83. Same case as in image no. 82, chromoscopy with indigo carmine.



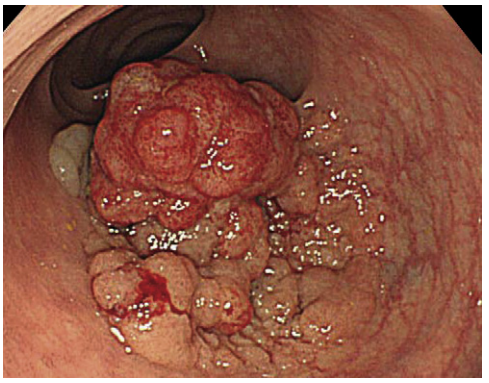
A86. Endoscopy, LST lesion, granular, homogenous, 0-IIa.



A87. Same case as in image no. 86, chromoscopy with indigo carmine.



A88. Endoscopy (magnification), NBI; LST lesion, granular, homogenous, 0-IIa, pit pattern type IV.



A89. Endoscopy, LST lesion, granular, mixed type, with irregular and sessile nodules, 0-Is + 0-IIa.

A90. Same case as in image no. 89, chromoscopy with indigo carmine.
